We study two recently proposed equations of state (EOS) which are obtained from high temperature QCD, and show how they can be adapted to use them for making predictions for relativistic heavy ion collisions. The method involves extracting equilibrium distribution functions for quarks and gluons from the EOS, which in turn will allow a determination of the transport and other bulk properties of the quark gluon plasma. Simultaneously, the method also yields a quasi particle description of interacting quarks and gluons. The first EOS is perturbative in the QCD coupling constant and has contributions of $O(g^3)$. The second EOS is an improvement over the first, with contributions up to $O(g^5 \ln (\frac{4}{g}))$; it incorporates the nonperturbative hard thermal contributions. The interaction effects are shown to be captured entirely by the effective chemical potentials for the gluons and the quarks, in both the cases. The chemical potential is seen to be highly sensitive to the EOS. As an application, we determine the screening lengths which are, indeed the most important diagnostics for QGP. The screening lengths are seen to behave drastically differently depending on the EOS considered, and yield, therefore, a way to distinguish the two equations of state in heavy ion collisions.

I. INTRODUCTION

Recent experimental results$^\dagger$ have indicated an ideal fluid, characterized by a small value of the viscosity to entropy density ratio, lying in the range 1.1 \sim 3.7, 8, 9; this range may be contrasted with the corresponding value for liquid helium (above superfluid transition temperature) which is close to ten$^{10}$. These observations signal the fact that the deconfined phase is strongly interacting, and are consistent with the lattice simulations$^{11}$, which predict a strongly interacting behavior even at temperatures which are a few $T_c$. In an attempt to appreciate this surprising result, interesting analogies have been drawn with ADS/CFT correspondence$^{12}$ and also with some strongly coupled classical systems$^{12}$. In any case, the emergence of the strongly interacting behaviour puts into doubt the credibility of a large body of analyses which are based on ideal or nearly ideal behaviour of QGP.

In this context, there is an interesting attempt by Arnold and Zhai$^{13}$ and Zhai and Kastening$^{14}$ who have determined the equation of state (EOS) of interacting quarks and gluons up to $O(g^3)$ in the coupling constant. This strictly perturbative EOS, which we henceforth denote by EOS1, has been improved upon by Kajantie et al.$^{15, 16}$ who have incorporated the contributions from the nonperturbative scales viz. $gT$ and $g^2 T$ and determined the EOS up to $O(g^5 \ln (\frac{4}{g}))$.$^{18}$ The latter will be denoted by EOS2. Subsequent studies$^{19, 20, 21}$ have emphasized the relevance of the above EOS to study quark gluon plasma. One would naturally wish to compare these EOS with (the fully non-perturbative) lattice results. EOS2 has been found$^{12}$ to be in qualitative agreement with the lattice results. It is not without interest to explore further whether this qualitative agreement can be further quantified, and whether HTL improved EOS can describe the QGP produced in heavy ion collisions. It is worthwhile noting the earlier attempts$^{22, 23, 24}$ that have been made to determine thermodynamic quantities such as entropy and the specific heat $c_v$ in improved perturbative approaches to QGP.

On the other hand, it is by now well established that the semiclassical approach is a convenient way to study the bulk properties of QGP$^{25, 26, 27, 28, 29}$, since they automatically incorporate the HTL effects$^{28, 29}$. There is a wealth of results which have been obtained within this framework$^{25, 26, 27}$, where the nonperturbative features manifest as effective mean color fields. These color fields have the dual role of producing the soft and semi soft partons, apart from modulating their interactions. The emergence of such effective field degrees of freedom, together with a classical transport has been indicated earlier by Blaizot and Iancu$^{30}$.

In this context, it is pertinent to ask if one could use heavy ion collisions to distinguish the various EOS and pick up the right one, by employing the semiclassical

\footnotesize{$^{\dagger}$vinode@iitk.ac.in
$^{\ddagger}$rojha@iitk.ac.in
$^{\vast}$vrazi@iitk.ac.in
framework involving an appropriate kinetic equation. The purpose of this paper is to explore such possibilities. As a first step in this direction, we shall show how the distribution functions underlying the proposed EOS can be extracted with a minimal ansatz, viz. effective chemical potentials for quarks and gluons. Once the distribution function is obtained, it can be used to study the bulk properties of the system such as chromo responses including the ubiquitous Debye Mass. Postponing all the other applications to a future work, we shall concentrate on determining the Debye mass through this procedure. As mentioned, we focus on EOS1 and EOS2. Both of them have been proposed for the case when the baryon number density vanishes. The corresponding chemical potentials are hence set to zero. There exist generalizations of the above EOS, proposed by Vuorinen [17] and more recently by Ipp et al [18], which allow for a finite baryon number. The two sets are applicable to distinct physical situations; the former (EOS1 and EOS2) are relevant to the QGP in the central midrapidity region of URHIC while the works of Ref. [17, 18] are applicable to peripheral collisions and/or when the so called nuclear transparency is only partial. An application of the above EOS to URHIC will be taken up separately.

This paper is organized as follows. In the next section, we extract the distribution functions for the gluons and the quarks from EOS1 and EOS2. We consider the pure gluonic case separately from the full QCD, by first setting \( N_f = 0 \). The (interacting) quark sector is then dealt with. In section III, the Debye mass is determined by employing the semiclassical method developed by Kelly et.al [28, 29]. In section III(B), we compare our results on screening length for EOS1 and EOS2 with the recent lattice results. We summarize the results and conclude in section IV. The appendix contains some details of calculations which are not explicitly given in the main text; it also lists some useful integrals.

**II. EXTRACTION OF THE DISTRIBUTION FUNCTIONS**

Recently Arnold et. al [13] have derived an equation of state (EOS1) for high temperature QCD up to \( O(g^5) \). EOS1 reads,

\[
P(1) = \frac{8\pi^2}{45 \beta} \left\{ (1 + \frac{21N_f}{32}) - \frac{15}{4} (1 + \frac{5N_f}{12}) \frac{\alpha_s}{\pi} + 30 (1 + \frac{N_f}{6}) \left( \frac{\alpha_s}{\pi} \right)^2 \right. \\
+ \left[ (237.2 + 15.97N_f - 0.413N_f^2 + \frac{135}{2} (1 + \frac{N_f}{6}) \ln \left( \frac{\alpha_s}{\pi} (1 + \frac{N_f}{6}) \right) \right] \\
- \frac{165}{8} (1 + \frac{5N_f}{12})(1 - \frac{2N_f}{33}) \ln \left( \frac{\bar{\mu}_{\text{MS}} \beta}{2\pi} \right) \left( \frac{\alpha_s}{\pi} \right)^2 \\
+ (1 + \frac{N_f}{6})^3 \left[ -799.2 - 21.99N_f - 1.926N_f^2 \\
+ \frac{495}{2} (1 + \frac{N_f}{6})(1 + \frac{2N_f}{33}) \ln \left( \frac{\bar{\mu}_{\text{MS}} \beta}{2\pi} \right) \left( \frac{\alpha_s}{\pi} \right)^2 \right] + O(\alpha_s^3 \ln(\alpha_s)).
\]

(EOS1)

that the latter are essentially nonperturbative, and contain contributions from scales \( T, gT \), and \( g^2T \). EOS2, which is thus determined up to \( O(g^5 \ln \frac{1}{g}) \), has the form

\[
P(2) = P(1) + \frac{8\pi^2}{45} T^4 \left[ 1134.8 + 65.89N_f + 7.653N_f^2 \\
- \frac{1485}{2} \left( 1 + \frac{1}{6}N_f \right) \left( 1 - \frac{2}{33}N_f \right) \ln \left( \frac{\bar{\mu}_{\text{MS}}}{2\pi T} \right) \left( \frac{\alpha_s}{\pi} \right)^3 \ln \frac{1}{\alpha_s}. \right.
\]

In the above expressions, \( N_f \) is the number of fermions, \( \alpha_s = g^2/(4\pi) \) is the strong coupling constant and \( \bar{\mu}_{\text{MS}} \) is the renormalization scale parameter in the \( \overline{\text{MS}} \) scheme.
Note that $\alpha_s$ runs with $\beta$ and $\mu_{\text{MS}}$. As remarked, the utility of this EOS in the context of QGP thermodynamics has been discussed earlier by Rebhan [21].

We now set to determine equilibrium distribution functions $<n_{q,f}>$ for the gluons and the quarks such that they would yield the EOS given above. The ansatz for the determination involves retaining the ideal distribution forms, with the chemical potentials $\mu_g$ and $\mu_f$ being free parameters. Note that for the massless quarks (u and d) which we consider to constitute the bulk of the plasma, $\mu \equiv 0$ if they were not interacting. This approach is of course not novel, since it underlies many of the ideas that attempt to describe the interaction effects in terms of the quasiparticle degrees of freedom. In the present context, we refer the reader to Ref. [31, 32], where an attempt is made to describe the lattice results in terms of effective mass for the partons.

We pause to note that the chemical potentials which we introduce are not the same as those which yield a nonzero baryon number density, as e.g., in [17, 18]. Here, the chemical potential merely serves to map the interacting quarks and gluons at zero baryon number chemical potential to noninteracting quasiparticles, viz., the dressed quarks and gluons. Their interpretation is, therefore, more akin to the effective mass, albeit as functions of the renormalization scale and temperature as we show below. Thus, the baryon number density of the plasma continues to vanish.

As the first step in our approach, we express the EOS in the form

$$P = P_g^I + P_q^I + \Delta P_g + \Delta P_f$$

(3)

The first two terms in the RHS of Eq. (3) are identified with the distributions of an ideal gas of quarks and gluons. The effects of the interaction in pure QCD are represented by $\Delta P_g$ and the residual interaction effects, by $\Delta P_f$. For the EOS which we are interested in, the identification of the above terms is straight forward. $\Delta P_g$ can be identified by first setting $N_f = 0$ and then subtracting the ideal part. The residual term is naturally identified as $\Delta P_f$ after subtracting the ideal part for quarks. In general the form of EOS (see Eq.(1) and Eq.(2))

$$P = \frac{8\pi^2}{45} \beta^{-4} \left[ 1 + A(\alpha_s) + B(\alpha_s) \ln \frac{\mu_{\text{MS}}\beta}{2\pi} + \frac{21}{32} N_f \right]$$

$$+ C(\alpha_s, N_f) + D(\alpha_s, N_f) \ln \frac{\mu_{\text{MS}}\beta}{2\pi}$$

(4)

where

$$P_g^I = \frac{8\pi^2}{45} \beta^{-4}$$

$$P_f^I = \frac{8\pi^2}{45} \beta^{-4} \frac{21}{32} N_f$$

$$\Delta P_g = A(\alpha_s) + B(\alpha_s) \ln \frac{\mu_{\text{MS}}\beta}{2\pi}$$

$$\Delta P_f = C(\alpha_s, N_f) + D(\alpha_s, N_f) \ln \frac{\mu_{\text{MS}}\beta}{2\pi}$$

(5)

For EOS1 the coefficients $A, B, C, D$ are denoted with a prime and are given by

$$A'(\alpha_s(N_f)) = \frac{15}{4} \alpha_s + 30 \frac{\alpha_s}{\pi} \beta^2 + (237.2 + \frac{135}{2} \log(\frac{\alpha_s}{\pi})^2 - 799.2 \frac{\alpha_s}{\pi} \beta^2$$

$$B'(\alpha_s(N_f)) = -\frac{165}{8} \frac{\alpha_s}{\pi} \beta^2 + \frac{495}{2} \frac{\alpha_s}{\pi} \beta^2$$

$$C'(\alpha_s(N_f), N_f) = \frac{15}{4} \left(1 + \frac{5}{12} N_f\right) \frac{\alpha_s}{\pi} + 30 \left(1 + \frac{1}{6} N_f\right) \left(\frac{\alpha_s}{\pi} \beta^2 + [237.2 + 15.97 N_f - 0.413 N_f^2 + \frac{135}{2} \ln(\frac{\alpha_s}{\pi})^2 + (1 + \frac{1}{6} N_f^2) \ln(\frac{\alpha_s}{\pi})^2 - A'(\alpha_s(N_f)) + 1.926 N_f^2 (\frac{\alpha_s}{\pi} \beta^2 - A'(\alpha_s(N_f))])$$

$$D'(\alpha_s(N_f), N_f) = \frac{165}{8} \left(1 + \frac{5}{12} N_f\right) \left(1 - \frac{2}{33} N_f\right) \left(\frac{\alpha_s}{\pi} \beta^2 \right) + \frac{495}{2} \left(1 + \frac{1}{6} N_f\right) \left(1 - \frac{2}{33} \frac{\alpha_s}{\pi} \beta^2 - B'(\alpha_s(N_f)) \right)$$

(6)

whereas for EOS2 the coefficients can be written in terms of the above primed coefficients for EOS1, as

$$A(\alpha_s(N_f)) = A'(\alpha_s(N_f)) + 1134.8 \frac{\alpha_s}{\pi} \beta^3 \log(\frac{1}{\alpha_s})$$

$$B(\alpha_s(N_f)) = B'(\alpha_s(N_f)) - \frac{1485}{2} \frac{\alpha_s}{\pi} \beta^3 \log(\frac{1}{\alpha_s})$$

$$C(\alpha_s(N_f), N_f) = C'(\alpha_s(N_f), N_f) + (65.89 N_f + 7.653 N_f^2) \frac{\alpha_s}{\pi} \beta^3 \log(\frac{1}{\alpha_s})$$
\[
D(\alpha_s(N_f), N_f) = D'(\alpha_s(N_f), N_f) - \frac{1485}{2} [(1 + \frac{1}{6}N_f)(1 - \frac{2}{33}N_f) - 1] (\frac{\alpha_s}{\pi})^3 \log(1 + \frac{1}{\alpha_s}).
\]

We seek to parametrize the contributions from all the non-ideal coefficients in terms the chemical potentials \(\mu_g\) and \(\mu_f\) for gluons and quarks respectively. Since the EOS have been proposed at high \(T\), with their validity being at temperatures greater than \(2T_c\) [33], we treat the dimensionless quantity \(\tilde{\mu}_{g,f} \equiv \beta \mu_{g,f}\) perturbatively. This approximation needs to be implemented self consistently, and accordingly, we expand the the grand canonical partition functions for gluons and quarks as a Taylor series in \(\tilde{\mu}_{g,f}\). We obtain the following expressions:

\[
\begin{align*}
\log(Z_g) &= \sum_{k=0}^{\infty} (\tilde{\mu}_g)^k \partial_{\tilde{\mu}_g}^k \log(Z_g)|_{\tilde{\mu}_g = 0} \\
\log(Z_q) &= \sum_{k=0}^{\infty} (\tilde{\mu}_f)^k \partial_{\tilde{\mu}_f}^k \log(Z_f)|_{\tilde{\mu}_f = 0}
\end{align*}
\]

where, \(Z_g\) and \(Z_f\) are given by

\[
\begin{align*}
Z_g &= \prod_p \frac{1}{(1 - \exp(-\beta \epsilon_p + \tilde{\mu}_g))}, \\
Z_q &= \prod_p \frac{1}{(1 + \exp(-\beta \epsilon_p + \tilde{\mu}_f))}.
\end{align*}
\]

We determine \(Z_g\) and \(Z_q\) (defined in Eq. (10)) up to \(O(\tilde{\mu}_{g,f})^3\). The truncation is seen to yield an accuracy of \(\sim\) ten percent when we consider EOS1. However, for the more physical EOS2, the agreement is within one percent. The gluon chemical potential \(\mu_g\) gets determined by

\[
\frac{A_g^{(3)}}{3!} (\tilde{\mu}_g)^3 + \frac{A_g^{(2)}}{2!} (\tilde{\mu}_g)^2 + A_g^{(1)} \tilde{\mu}_g - \Delta P_g \beta V = 0.
\]

Similarly, the equation determining \(\mu_f\) reads:

\[
\frac{A_f^{(3)}}{3!} (\tilde{\mu}_f)^3 + \frac{A_f^{(2)}}{2!} (\tilde{\mu}_f)^2 + A_f^{(1)} \tilde{\mu}_f - \Delta P_f \beta V = 0
\]

The coefficients \(A_g^{(n)}\) and \(A_f^{(n)}\) are given by

\[
\begin{align*}
A_g^{(n)} &= \partial_{\tilde{\mu}_g}^n \log(Z_g)|_{\tilde{\mu}_g = 0} \\
A_f^{(n)} &= \partial_{\tilde{\mu}_f}^n \log(Z_f)|_{\tilde{\mu}_f = 0}
\end{align*}
\]

The explicit forms of \(A^n\) up to \(n = 3\) are listed in the Appendix.

### A. Explicit evaluation of the chemical potential

Before we discuss the solution of Eq. (10) and Eq. (11), it is instructive to evaluate \(\mu_{g,f}\) with just the linear and quadratic terms for the sake of comparison. In the linear order, the solutions read

\[
\tilde{\mu}_g = \frac{8\pi^2}{45(A_g^{(1)}/f)} [A(\alpha_s) + B(\alpha_s) \ln \frac{\bar{\mu}_{MS}\beta_s}{2\pi}]
\]

\[
\tilde{\mu}_f = \frac{8\pi^4}{45(A_f^{(1)}/f)} [C(\alpha_s) + D(\alpha_s) \ln \frac{\bar{\mu}_{MS}\beta_s}{2\pi}]
\]

while, in the next to the leading order, the solution has the form

\[
\tilde{\mu}_g = -\frac{A_g^{(1)}}{A_g^{(2)}} \pm \sqrt{\left(\frac{A_g^{(1)}}{A_g^{(2)}}\right)^2 + C_g}
\]

\[
\tilde{\mu}_f = -\frac{A_f^{(1)}}{A_f^{(2)}} \pm \sqrt{\left(\frac{A_f^{(1)}}{A_f^{(2)}}\right)^2 + C_f}
\]

where, \(C_g = 2\Delta P_g \beta V / A_g^{(2)}\) and \(C_f = 2\Delta P_f \beta V / A_f^{(2)}\). Finally, the exact solutions can be obtained by using well known algebraic techniques. Since the explicit algebraic solutions do not have an illuminating form, we show the solutions graphically instead in the next subsection.

The distribution functions for the gluons and the quarks get determined, in terms of the chemical potentials, through

\[
\langle n_g \rangle_p = \frac{\exp(-\beta \epsilon_p + \tilde{\mu}_g)}{1 - \exp(-\beta \epsilon_p + \tilde{\mu}_g)}
\]

\[
\langle n_f \rangle_p = \frac{\exp(-\beta \epsilon_p + \tilde{\mu}_f)}{1 + \exp(-\beta \epsilon_p + \tilde{\mu}_f)}
\]

The extraction of the distribution functions is, nevertheless, incomplete. For, the EOS – and hence the chemical potentials – depend on the renormalization scale. On the other hand, the physical observables should be scale independent. We circumvent the problem by trading off the dependence on \(\bar{\mu}_{MS}\) to a dependence on the critical temperature \(T_c\). To that end, we exploit the temperature dependence of the coupling constant \(\alpha_s(T)\) [33, 34] and of renormalization scale:

\[
\bar{\mu}_{MS}(T) = 4\pi T \exp(-\gamma_E + 1/22)
\]

\[
\alpha_s(T) = \frac{1}{8\pi b_0 \log(T/\lambda_T)} = \alpha_s(\mu^2)|_{\mu = \bar{\mu}_{MS}(T)}
\]

\[
\lambda_T = \frac{\exp(\gamma_E + 1/22)}{4\pi} \lambda_{MS}
\]
where, $b_0 = 33 - 2N_f/12\pi$ and $\lambda_{MS} = 1.14T_c$. With this step, the distribution functions get determined completely, and are obtained as functions of $T/T_c$.

We note that the results presented below, being valid for $T > 2T_c$, need to be supplemented by a similar analysis for EOS which are valid for $T \sim T_c$. Such an analysis does indeed exist, along the lines of this paper [32], who have considered the lattice EOS. They do not determine the Debye mass, but focus on the impact of the EOS on the flow parameters in heavy ion collisions.

Although, EOS1 and EOS2 have been computed within the framework of weak coupling technique but they give convergent results for the temperature ranges which are more than $5T_c$. We shall see in the next Sub-section that these equations of state are far away from their ideal behaviour up to the extent that they can be utilized to make definite predictions for QGP.

### B. Hot QCD EOS vs Ideal EOS

As a warm up, we compare EOS1 and EOS2 with the ideal EOS by plotting the ratio $R = \frac{\tilde{\rho}}{\rho}$, as functions of temperature, in Figs.1,2.

![FIG. 1: (color online) Behaviour of R with temperature for EOS1](image)

The most striking feature that we see is the large sensitivity to the inclusion of the $g^3 \ln(\frac{1}{g})$ contributions. It is most pronounced in the behaviour of pure QCD where major qualitative and quantitative differences appear: (i) For EOS1, $R$ increases with $T$, in contrast to EOS2 which where it decreases from above, approaching the same asymptotic value for large $T$; (ii) interestingly, the non-perturbative (and higher order) corrections makes the system less non-ideal. Indeed, EOS1 yields values of $R$ which are $10 - 45$ percent away from the ideal value 1, in contrast to EOS2 (see Fig2), for which $R$ is only $2 - 8$ percent away from the ideal value. Incidentally, the above observation implies that the expansion in Eq.5 works better for EOS2 than the former. This will be reflected later in the behavior of effective chemical potentials with temperature. We shall further see that, smaller the value of $|\bar{\mu}_{g,f}|$, better will be the approximation.

### C. The chemical potentials

The variation of the effective chemical potentials with renormalization scale at a fixed temperature has already been studied in reference [14]. We prefer to recast it into a dependence of $\tilde{\mu}_{g,f}$ on $\frac{T}{T_c}$ (see the previous subsection) since it is more relevant to the study of QGP in heavy ion collisions. This is shown in Figs. 3 – 8, where the contributions coming from linear, quadratic and cubic approximations in the Taylor series(Eq.4) are individually displayed, for both EOS1 and EOS2. These figures exhibit, in essence, all the interaction effects.

A number of features emerge from examining Figs. 3 – 8. Consider EOS1 first. Here, the linear approximation does reasonably well for pure QCD, but fails badly in the quark sector. The chemical potential is negative in both the sectors, and approaches the ideal value asymptotically from below. In contrast, EOS2 leads to a different behaviour: $\tilde{\mu}_g$ starts with a small positive value at $T \sim 2T_c$, and stays essentially so until $T \sim 13T_c$, and switches sign to acquire a small negative value. Since the magnitude remains less than 0.1 throughout, the deviation from the ideal behaviour is minimal. $\tilde{\mu}_f$ remains negative (with the maximum magnitude $\sim 0.25$ at $T = 2T_c$), which is about a factor four smaller in comparison with the corresponding value from EOS1. The interaction effects get manifestly stronger as we increase the number of flavors.

It is significant that the ideal value is not reached even at $T \sim 10T_c$, which indicates that the phase remains interacting. We also note that our method of extracting
the chemical potential works more efficiently for EOS2, as indicated by small corrections from higher order terms to the linear estimate.

III. THE DEBYE MASS AND SCREENING LENGTH

The extraction of the equilibrium distribution functions affords a determination of the Debye mass, via the semiclassical transport theory [29]. The Debye mass controls the number of bound states in heavy $q\bar{q}$ systems, yields the extent of $J/\Psi$ suppression in heavy ion collisions, provided that we have a reliable estimate of the temperature of the plasma. Even otherwise, the qualitative significance of the Debye mass cannot be overestimated since the deconfined phase remains strongly interacting even at large $T$.

The determination of $m_D$ is straightforward if we employ the classical transport theory [29]. It is simply given by

$$M^2_{g,f} = g'^2 C_{g,f} \int \frac{d}{dp_0} < n_{g,f} > d^3p.$$  \hspace{1cm} (19)
\[ M^2_{g, id} = M^2_{g, hot} + M^2_{f, hot} = \frac{(N + N_f/2)}{3} g^2 \beta^{-2}. \]  

The hot QCD EOS modify the above expression; it is easy to see, from Eqs. (19) and (20) that the new Debye masses, scaled with respect to their respective ideal values get determined, in terms of the standard PolyLog functions\(^[43]\) by

\[ M^2_{g, hot} \equiv \frac{6}{\pi^2} PolyLog[2, \exp(\tilde{\mu}_g)] = F_1(\tilde{\mu}_g) \]

\[ M^2_{f, hot} \equiv -\frac{12}{\pi^2} PolyLog[2, -\exp(\tilde{\mu}_f)] = F_2(\tilde{\mu}_f). \]  

Consequently, the expression for the total relative mass is obtained as

\[ \frac{M^2_{hot}}{M^2_{id}} = \frac{\frac{N}{3} F_1(\tilde{\mu}_g) + \frac{N_f}{6} F_2(\tilde{\mu}_f)}{(N/3 + N_f/6)}. \]  

It is, however, more convenient to plot the inverse debye mass i.e., the screening length as a function of \( T/T_c \).

### A. Relative screening lengths

We first establish the notations. Let \( \lambda_h \) denote the screening length generated by the hot EOS. Let \( \lambda_{id} \) be the screening length of an ideal qgp. It is convenient to consider also the contribution coming from the pure QCD sector, whose screening lengths we denote by \( \lambda^g_h \) and \( \lambda^g_{id} \) respectively.

The behaviour of the screening lengths is shown in Figs. 9-12. As in the case of the chemical potentials, the dependence on the order of perturbation is striking here as well. For EOS1 where the contributions up to \( O(g^5) \) are included, the screening lengths in the full QCD as well as pure QCD remain nonzero. The dominant contribution is from the gluonic sector, which dominates over the quark sector, as may be seen in Fig.9 where we plot the ratio \( R_{h/g} = \lambda_h/\lambda^g_h \), which is in excess of 0.7 throughout. Note, however, that the relative dominance gets weaker as we increase the number of flavors. Fig.10 shows the variation of the ratio \( R_{h/id} = \lambda_h/\lambda_{id} \) as a function of temperature. Interestingly, the interaction is seen to weaken the screening, and so does an increase in the number of flavors.

These results are in sharp contrast with the case of EOS2, which we recall has nonperturbative \( O(g^6 \ln(1/g)) \) contributions. These are shown in Figs.11 and 12. It is clear from Fig 11 that the contribution from the pure gluonic sector saturates the contribution to the screening all...
the way up to temperatures $T \sim 13T_c$, and drops sharply thereof. This feature is reinforced by Fig. 12 where the ratio $R_{h/id}$ stays at zero between $2T_c$ and $12 - 13T_c$. It is of a purely academic interest that the screening length should become non-zero beyond $12T_c$.

It appears that the perfect screening is indeed the strongest prediction of EOS2 and must be most easily tested in heavy ion collisions, where temperatures up to $3T_c$ are expected at LHC. This is in sharp contrast with the assumptions of a near ideal behaviour, and also some theoretical analyses which in fact propose an enhanced production of $J/\Psi$ at LHC energies [40]. We, therefore, attempt to compare these predictions with the lattice results below.

### B. Comparison with the lattice results

In this subsection, we compare our results on screening length of EOS1 and EOS2 with the lattice results. Lattice computations extract the screening lengths from the quark-antiquark free energies. To be concrete, we make the comparison with three distinct values of the coupling constant, $g' = 0.3, 0.5, 0.8$.

Further, we consider three cases, (i) pure QCD, (ii) $N_F = 2$ and (iii) $N_F = 3$. To facilitate a proper comparison, we take the respective transition temperatures to be $T_c = 270MeV$, $203MeV$ and $195MeV$, as given by lattice computations. The comparison is shown only with EOS1 since EOS2 predicts absolute screening in the range $2T_c < T < 12T_c$ that we are interested in. The results are shown in Figs. 13-15. As observed, the screen-
lengths which are smaller in value, except for $g'\sim 0.7$, to get quantitative. The lattice results predict screening the number of flavours. However, the agreement fails the dependence on the coupling constant as well as on EOS2 which has interactions up to $O(g^6 \ln(1/g))$ contributions, and exhibited most vividly by the screening length. Surprisingly, the lattice screening length is measured in $fm$ than the EOS1 results. Indeed, the lattice screening length is $\sim 0.7 fm$ in the vicinity of $T_c$, and drops to $\sim 0.4 fm$ close to $2T_c$. It is evident from Figs. 13-15 that the results of EOS1 are $3-10$ times higher in value. Any better agreement with a further increase in the value of $g'$ is ruled out since $g' \leq 1$ necessarily.

\section{IV. CONCLUSIONS AND OUTLOOK}

In conclusion, we have extracted the distribution functions for gluons and quarks from two equations of state, in terms of effective chemical potentials for the partons. The chemical potentials are shown to be highly sensitive to the inclusion of $O(g^6 \ln(1/g))$ contributions, and exhibited most vividly by the screening length. Surprisingly, EOS2 which has interactions up to $O(g^6 \ln(1/g))$ shows less nonideal behaviour compared to EOS1 (which has contributions up to $O(g^5)$). Equally strikingly, the plasma corresponding to EOS2 is predominantly gluonic, in the sense that the Debye mass from the gluonic sector diverges in the range $2T_c \leq T \leq 12T_c$. This result is in contrast with the less precise EOS1, where the gluonic contribution is not that overwhelming.

To place our analysis in perspective, we note that our analysis is based on but two equations of state, neither of which has full non-perturbative contributions. Nevertheless, it may not be without merit since EOS2, for instance, makes rather strong predictions which may be tested; EOS1 is, on the other hand, seen to be in qualitative agreement with the lattice results. Indeed, the work does provide a platform to study quantitatively the import of the EOS to heavy ion collisions in a quantitative manner. Experiments at LHC may be able to probe these EOS since a temperature in the range $T \sim 2 - 3T_c$ is expected to be achieved there. More importantly, the method developed here can be easily employed to study more precise EOS (as from lattice computations), or more general EOS (as the inclusion of baryonic chemical potentials). To be sure, an incisive analysis is possible only after studying other quantities such as the viscosity, its anomalous component $\eta_s/\zeta$, the viscosity to entropy ratio, and the specific heat. Finally, the insertion of the appropriate equilibrium distribution functions in the semiclassical transport equations allow for studying (i) the production and the equilibration rates for the QGP in heavy ion collisions $[25, 26, 27]$, and (ii) the color response functions $[42]$, of which the Debye mass is but one limiting parameter. These will be taken up in subsequent publications. These investigations will be taken up separately.

\section{V. ACKNOWLEDGMENTS}

We thank DDB Rao for assistance with numerical work. Two of us, VC and RK, acknowledge CSIR (India) for financial support through the award of a fellowship.
VI. APPENDIX

We use the following standard integrals while extracting effective chemical potential:

\[
\int_0^\infty p^2 \exp(-p) \frac{(1 - \exp(-p))^3}{(1 - \exp(-p))^3} dp = 2(1 + \sum_{n=1}^{\infty} \frac{1}{(n + 1)^3} \prod_{k=1}^{n} \frac{3 + k - 1}{k!})
\]

\[
\int_0^\infty p^2 \exp(2p) \frac{(1 + \exp(p))^3}{(1 + \exp(p))^3} dp = \frac{\pi^2}{12} + \log(2)
\]

\[
\int_0^\infty p^2 \exp(p) \frac{(1 - z \exp(p))^2}{(1 + z \exp(p))^2} dp = \text{PolyLog}[2, z]
\]

\[
\int_0^\infty p^2 \exp(p) \frac{(1 + z \exp(p))^2}{(1 + z \exp(p))^2} dp = -\text{PolyLog}[2, -z]
\]

The coefficients in the perturbative expansion of \( \log(Z_g) \) and \( \log(Z_f) \) are as follows:

\[
A^{(1)}_g = \frac{V}{2\pi^2 g_b} 2\zeta(3)
\]

\[
A^{(1)}_f = \frac{V}{2\pi^2 g_f} 3 \zeta(3)
\]

\[
A^{(2)}_g = \frac{V}{2\pi^2 g_b} 2 \frac{\pi^3}{3}
\]

\[
A^{(2)}_f = \frac{V}{2\pi^2 g_f} \frac{\pi^3}{6}
\]

\[
A^{(3)}_g = \frac{V}{2\pi^2 g_b} 2 \log(2)
\]

\[
A^{(3)}_f = \frac{V}{2\pi^2 g_f} [4(1 + \sum_{n=1}^{\infty} \frac{1}{(n + 1)^3} \prod_{k=1}^{n} \frac{3 + k - 1}{k!}) \frac{(\pi^2}{3}]
\]

where \( g_b = 8 \times 2 \) and \( g_f = 6N_f \) are the degeneracy factors for gluons and quarks.

The expression for the QCD running coupling constant displayed in Eq. (13) is allowed in the region where the weak perturbative techniques are valid. Since, the weak coupling techniques give convergent results for more than $2T_c$, where $T_c$ is QCD transition temperature and a free parameter here. In this region, we can consider the asymptotic limit of the running coupling constant. Employing this, we shall see that the hot QCD EOS relative to ideal EOS and Effective Chemical Potentials scales with $T/T_c$.

The function $\text{PolyLog}[2, z]$ is defined by the series $\text{PolyLog}[2, z] = \sum_{k=1}^{\infty} \frac{z^k}{k^2}$, with a radius of convergence given by $|z| < 1$.
