Abstract. Angiotensin II (Ang II) is a well-known peptide that maintains the balance of electrolytes in the higher vertebrates. Ang II stimulation in the adrenal gland induces the synthesis of mineralocorticoids, mainly aldosterone, through the up-regulation of aldosterone synthase (CYP11B2) gene expression. Additionally, it has been reported that Ang II activates multiple signaling pathways such as mitogen-activated protein kinase (MAPK) and Ca²⁺ signaling. Although Ang II has various effects on the cellular signaling in the adrenal cells, its biological significance, except for the aldosterone synthesis, is still unclear. In this study, we attempted to search the novel target gene(s) of Ang II in the human adrenal H295R cells using a proteomic approach combined with stable isotopic labeling using amino acid in cell culture (SILAC). Interestingly, we found that Ang II stimulation elevated the expression of phosphofructokinase type platelet (PFKP) in both protein and mRNA levels. Moreover, transactivation of PFKP by Ang II was dependent on extracellular-signal-regulated kinase (ERK) 1/2 activation. Finally, we observed that Ang II treatment facilitated glucose uptake in the H295R cells. Taken together, we here identified PFKP as a novel target gene of Ang II, indicating that Ang II not only stimulates steroidogenesis but also affects glucose metabolism.

Key words: Angiotensin II, Adrenocortical cell, Proteome analysis, Phosphofructokinase type platelet

ANGIOTENSIN II (ANG II) is a bioactive peptide, and is essential for the maintenance of the balance of electrolytes in the higher vertebrates [1]. The secretion of this peptide is stringently controlled by several enzymes, such as renin and angiotensin-converting enzyme (ACE) [2]. In the adrenal gland, Ang II stimulates zona glomerulosa which is the external layer of the adrenal cortex and facilitates the transcription of steroidogenic enzymes including steroid 21-hydroxylase (CYP21A) [3], 3β-hydroxysteroid dehydrogenase (HSD3β) [4], and aldosterone synthase (CYP11B2) [5]. These enzymes synthesize aldosterone, a major mineralocorticoid, that enables the kidney to reabsorb salt and water [6]. Through these sequential reactions, named as the renin-angiotensin-aldosterone system (RAAS), Ang II plays an important role in the mineral homeostasis.

In the adrenal zona glomerulosa, Ang II stimulates various signaling pathways via the Ang II type I receptor (AT1R) that belongs to the G protein-coupled receptor (GPCR) family [7]. Like other GPCRs, AT1R activates inositol triphosphate (IP3) signaling and releases Ca²⁺ from the endoplasmic reticulum. Then, the cytosolic Ca²⁺ activates Ca²⁺/calmodulin-dependent protein kinase (CaMK) and protein kinase C (PKC) [8]. Moreover, AT1R also activates mitogen-activated protein kinase (MAPK) signaling, such as extracellular-signal-regulated kinase (ERK) [9] and p38 signaling [10]. Therefore, Ang II can activate multiple cellular signaling pathways. However, the biological significance of Ang II in the adrenal gland remains poorly understood except for mineralocorticoid synthesis.

Proteome analysis using mass spectrometry is a powerful tool for the comprehensive analysis of gene expression. Several studies have been carried out to
search for the target genes of Ang II in H295R cells derived from human adrenocortical tumor by microarray analysis [11, 12]. However, there remains a possibility that the analysis of mRNA expression does not reflect the actual gene expression since they are not only controlled by transcriptional efficiency and mRNA stability but also by translational efficiency and protein stability. With regards to these aspects, proteomic analysis is a method to directly measure gene expression. Moreover, the recent development of mass spectrometry technology combined with isotopic labeling of proteins (SILAC) can perform a more quantitative comparison of protein expression [13]. In the present study, we explored the novel target gene of Ang II in the adrenal cortical cells using SILAC-based proteomic analyses to define the unknown effect of Ang II in the adrenal gland.

Materials and Methods

Cell culture

Human H295R cells were cultured in a DMEM/Ham F-12 medium (Fujifilm Wako Pure Chemical, Osaka, Japan) including 4.18 mM potassium chloride supplemented with 10% fetal bovine serum (FBS), insulin-transferrin-selenium-G (ITS) supplements (Thermo Fisher Scientific, Pittsburgh, PA, USA), 1.25 mg/mL of BSA (Sigma-Aldrich St Louis, MO, USA), 5.35 μg/mL of linoleic acid (LA, Sigma-Aldrich), 100 U/mL of penicillin, and 100 μg/mL of streptomycin. This cell line was grown at 37°C in 5% CO₂. For Ang II stimulation, H295R cells were incubated in DMEM (Fujifilm Wako) containing 1% charcoal-treated FBS and antibiotics with angiotensin II (Sigma-Aldrich).

Stable isotope labeling using amino acids in cell culture (SILAC)-based quantitative proteomic analysis

According to a previous report [14], H295R cells were cultured in RPMI media (Thermo Fisher Scientific) supplemented with 10% dialyzed FBS, ITS, BSA, LA, and antibiotics. The medium was also supplemented with normal lysine and arginine to create a “light” medium in one culture, or 13C6, 15N2-lysine and 13C6-arginine (Fujifilm Wako) to create a “heavy” medium in another culture. After the cells were cultured in these media for 3 weeks, the cells that were cultured in the heavy medium were treated with 100 nM Ang II, whereas the cells in light medium were not treated. For the preparation of cell extracts, the collected cells that were cultured in heavy/light conditions were mixed in the same tube, lysed by sonication in TNE buffer (20 mM Tris-HCl, 137 mM NaCl, 2 mM EDTA, 1% NP-40, and protease inhibitor cocktail III (pH 7.9) (Merck Millipore, Burlington, MA, USA), and the debris was removed by centrifugation. These extracts were subjected to SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and visualized by colloidal blue staining (Thermo Fisher Scientific). Each sample was dissected into approximately 30 sections, and subjected to a trypsin in-gel digestion procedure, as previously described [15]. The spectrum of the digested peptides was measured by nano LC-ESI-MS/MS using an LTQ Velos Orbitrap ETD instrument (Thermo Fisher Scientific). The spectral data were processed by a Mascot search (MATRIX SCIENCE, London, UK) to identify proteins, and by Proteome Discoverer (Thermo Fisher Scientific) to calculate the protein expression ratio. We excluded the data that is not satisfied with the false discovery rate (FDR) of peptide <0.01 and the number of peptide spectrum match (PSM) of protein ≥2.

Computational clustering and gene ontology (GO) analysis

The protein expression ratio was analyzed by Perseus software [16] to determine the differentially expressed proteins (p < 0.01). The differentially expressed protein lists by Ang II treatment for 6, 12, or 24 hours were merged to define 161 proteins that altered the expression in at least one condition. For the 161 proteins, pair-wise Pearson correlation coefficients of expression ratios were computed for 6, 12, and 24 hours treatments. The distant matrix was defined as 1-Pearson correlation coefficients, which ranged from 0 to 2 when the pair gave perfect or inversely perfect correlation, respectively. Hierarchical clustering was performed using Ward’s method of R and gplots package (R.C. team, R: A Language and Environment for Statistical Computing, https://www.r-project.org/, 2015.). G. Warne, B. Bolker, L. Bonebakker, R. Gentleman, W. Huber, A. Liaw, T. Lumley, M. Maechler, A. Magnusson, S. Moeller, M. Schwartz, and B. Venables, gplots: Various R Programming Tools for Plotting Data. (2015). GO analysis was carried out using the DAVID bioinformatics suite (version 6.7) [17].

Western blotting and antibodies

Western blotting analysis was carried out using α-PFKP (Cell Signaling Technology, CST, Danvers, MA, USA), α-actin (Santa Cruz Biotechnology, Dallas, TX, USA), α-ERK1/2 (CST), and α-phospho ERK1/2 (CST). Densitometric analysis was obtained by Image J software.

RNA isolation, complementary DNA (cDNA) synthesis, polymerase chain reaction (PCR), and statistics

RNA isolation, cDNA synthesis and PCR were conducted as previously described [15]. The primer sequences for the human genes were as follows: 1) PFKP,
forward, 5'-CTACAAAGCGACGTGCCATCAG-3', and reverse, 5'-ATCATAGATGGCCAGACATCC-3'. We attempted to survey the novel target genes of Ang II with SILAC-based quantitative proteomic analysis in the present study. The cells cultured in the “heavy” labeled medium were stimulated by 100 nM Ang II for 6, 12, or 24 hours and the cells were combined with the control cells, which were harvested in the “light” medium without Ang II. Then, the extracts derived from these cells were subjected to SDS-PAGE and mass spectrometric analysis (Fig. 1A). The results show that 3,464, 4,145, and 4,653 proteins were identified and satisfied our criteria (see Materials and methods) in 6, 12, and 24 hours samples, respectively (Fig. 1B). These experiments revealed the existence of unknown Ang II target genes in addition to the genes already known as an Ang II target such as RHOB (Table 1) [11].

Furthermore, clustering analysis divided the proteins into the four groups, which altered the expression with a statistically significance difference ($p < 0.01$) (Fig. 1C). We focused on cluster 3 whose expression increased depending on the treatment time (Fig. 1D). This cluster was also subjected to the gene ontology (GO) analysis. GO analysis revealed that the proteins grouped as cluster 3 were related to the “fructose 1,6-bisphosphate metabolic process ($p = 0.013$)” and the “fructose metabolic process ($p = 0.042$)” (Fig. 1E). Fructose metabolism plays a major role in glucose metabolism, particularly in glycolysis [19]. Therefore, we examined the expression changes that were focused on the proteins related to glycolysis (Table 2A). After 24 hours from Ang II stimulation, the expression of several glycolysis-related proteins such as HK1, HK2, TPI, ENO1 were slightly increased (about 1.2-fold) and PFKP and ALDOC expressions were especially up-regulated with a statistically significance difference (1.52-fold and 1.34-fold, respectively). Compared to this result, the expressions of pentose phosphate pathway (PPP)-related proteins did not change (Table 2B). These results suggested that Ang II stimulation did not increase the PPP-related proteins, but specifically raised the glycolysis-related proteins PFKP and ALDOC.

**PFKP is a novel Ang II target gene in the protein/ mRNA levels**

We validated the incremental PFKP expression by Ang II treatment. Western blotting combined with densitometric analysis showed a 1.74-fold upregulation of PFKP, while the expression of actin changed very little (1.07-fold) (Fig. 2A). Three independent experiments indicated that the PFKP/actin ratio increased 1.68-fold (Fig. 2B). This agreed with the mass spectrometry analysis (Table 2). Next, we examined whether this PFKP expression change was in protein or mRNA levels. RT-qPCR analysis showed an incremental change in PFKP mRNA expression at 6, 12, and 24 hours treatment (Fig. 2C). The phosphofructokinase family is composed of PFKP (platelet type), PFKM (muscle type), and PFKL (liver type). Hence, we investigated the alteration of PFKM and PFKL mRNA expression levels. These results showed that the mRNA expression levels of PFKM and PFKL were not increased by Ang II stimulation (Fig. 2D and 2E), which were in agreement with mass spectrometry analysis (Table 2). Taken together, we considered that PFKP is a novel Ang II-response gene both in mRNA- and protein-levels. We next examined whether 1% charcoal-treated FBS affected PFKP mRNA expression by Ang II stimulation. As shown in Fig. 2F, Ang II-stimulated PFKP mRNA expression level in the presence of 1% charcoal-treated FBS was identical to that in the absence of FBS, indicating that 1% charcoal-treated FBS did not affect it.

**Results**

**Proteomic analysis to identify the novel target genes of angiotensin II**

In the adrenal gland, it is well known that Ang II stimulates various signaling pathways such as Ca$^{2+}$/CaMK and MAPK signaling as well as governing aldosterone synthesis [7, 18]. However, less is known about the other functions of Ang II in the adrenocortical cells. Therefore, we attempted to survey the novel target genes of Ang II with SILAC-based quantitative proteomic analysis in the present study. The cells cultured in the “heavy” labeled medium were stimulated by 100 nM Ang II for 6, 12, or 24 hours and the cells were combined with the control cells, which were harvested in the “light” medium without Ang II. Then, the extracts derived from these cells were subjected to SDS-PAGE and mass spectrometric analysis (Fig. 1A). The results show that 3,464, 4,145, and 4,653 proteins were identified and satisfied our criteria (see Materials and methods) in 6, 12, and 24 hours samples, respectively (Fig. 1B). These experiments revealed the existence of unknown Ang II target genes in addition to the genes already known as an Ang II target such as RHOB (Table 1) [11].

Top 10 proteins which increased their expression by Ang II stimulation at respective time point. The proteins are listed in order from 1 to 10 according to their increased expression ratio each 6 (a), 12 (b) and 24 (c) hours from Ang II stimulation. “H/L Count” means the number of spectra to calculate H/L Ratio.

Ang II response of PFKP was dependent on MEK/ERK signaling

In the adrenal gland, Ang II activated several signaling pathways via its receptor, AT1R. So far, classical MAPK, p38 MAPK, and Ca\(^{2+}\)/CaMK signaling were reported to be activated by Ang II stimulation in H295R cells [18]. Then, we attempted to reveal the signaling cascades involved in the upregulated expression of PFKP by Ang II. The PFKP upregulation responding to Ang II was critically repressed with U-0126, which is an inhibitor of classical MAPK signaling via MEK/ERK, while the p38 MAPK signaling inhibitor SB203580 and CaMK2 inhibitor KN-93 did not suppress the expression (Fig. 3A and 3B). These results suggested that Ang II stimulation increased the PFKP mRNA through MEK/ERK signaling.

Ang II affected the glucose intake in the adrenal cells

As shown in this paper, we identified the PFKP as a new response gene of Ang II (Table 2 and Fig. 2). PFKP is a member of the phosphofructokinase family which catalyzes the phosphorylation of fructose-6-phosphate to fructose-1,6-bisphosphate [20]. This reaction is considered as a rate-limiting step in glycolysis [21]. Therefore, we postulated that Ang II stimulation influenced glucose metabolism. We therefore examined the glucose concentration of the cultured medium in H295R cells. The concentration of glucose was significantly decreased in the medium after the cells were cultured with Ang II stimulation for 72 hours (Fig. 4A). Next, we checked the effect of Ang II on cell growth to calculate the glucose uptake per total cell number. A previous report showed that Ang II stimulated the cell cycle into progression during short-term treatment in H295R cells [22]. However, in our experiments, cell growth had a tendency to be slightly suppressed by Ang II treatment for 36 and 72 hours, though there was no statistical significance (Fig. 4B). Taken together, by calculating the glucose uptake per total cell number, we confirmed that Ang II stimulation increased the amount of glucose uptake (Fig. 4C).

Discussion

Although Ang II is well known as a bioactive peptide to induce aldosterone synthesis, little is known about its other effects on the adrenal gland. Previous studies investigated the target genes of Ang II in the adrenal cortical H295R cell line or primary cultured adrenal cells using microarray analysis [11, 12]. These reports focused on the early response genes belonging to transcription factors and the other target genes of Ang II remain elusive especially for more than 12 hours treatment. In this
study, we attempted to reveal novel targets of Ang II in adrenal H295R cells using proteomic analysis. H295R cells are derived from a human adrenocortical carcinoma, and are well known to preserve hormonal responses to Ang II and potassium [23]. Our results of SILAC-based quantitative proteomic analysis identified more than three thousand proteins that satisfied our criteria in each sample (Fig. 1B). For investigation of the long-span effect of Ang II treatment, we selected cluster 3 which increased the expression over time and they were subjected to GO analysis. The result of GO analysis indicated that the proteins including cluster 3 were involved in fructose metabolism which is a part of the glycolysis pathway (Fig. 1E, Table 2A). Taken together, we focused on and analyzed the expression changes of the PFKP protein responding to Ang II stimulation.

Analysis of PFKP mRNA expression showed that the increase of the PFKP protein by Ang II stimulation was due to transcriptional activation (Fig. 2C).

tional regulation of the PFKP gene. Previous work showed that Krüppel-like factor 4 (KLF4) directly bound to the promoter of PFKP and activated its transcription [24]. More recently, transcriptional repressor ZBTB7A was reported to reduce the expression of PFKP in vivo and in vitro [25]. In this study, we found that MEK inhibitor U-0126 significantly repressed the up-regulation of PFKP mRNA by Ang II stimulation (Fig. 3A). MEK inhibition reduced ERK1/2 phosphorylation (Fig. 3B) and led to a decrease in the phosphorylation and activation of ERK1/2-targeted transcription factors [26]. Therefore, our results indicated that Ang II stimulation facilitated the transcription of PFKP via ERK1/2 activation, which is well known to be involved in Ang II-mediated cell proliferation [27]. However, the activation of ERK1/2-targeted transcription factors, such as ATF1

Fig. 2 Ang II raised the expression of PFKP in protein and mRNA levels.

(A) The validation of the alteration of PFKP expression by western blotting. The numbers under each panel indicated the expression ratio measured by Image J. (B) Densitometric analysis was carried out based on the results from three independent experiments as in (A). (C–E) RT-qPCR was conducted using the primers for PFKP (C), PFKM (D), PFKL (E) and for GAPDH as a control. (F) RT-qPCR was conducted under the condition of H295R cells were stimulated by Ang II either with 1% stripped FBS or without FBS. RT-qPCR intensities were normalized to GAPDH expression. Data are represented as means ± standard deviations (n = 3), ratio to non-treated (NT, without Ang II) groups. * p < 0.05; ** p < 0.01.
and CREM, were reported to be phosphorylated by Ang II stimulation as the fast reaction in H295R cells. In particular, the phosphorylation of these transcription factors peaked at 5 minutes from the addition of Ang II and was attenuated at 6 hours [28]. We showed that the transcriptional activation of PFKP occurred after 6 to 24 hours from Ang II treatment (Fig. 2C). Based on these findings, we presumed that the transcription of PFKP was not directly enhanced by the ERK1/2-targeted transcription factor like CREB, but other transcription factors, for example KLF4 or ZBTB7A, might mediate between ERK1/2 activation and the transactivation of PFKP.

Then, we showed that Ang II up-regulated glucose uptake in H295R cells (Fig. 4). These results indicated the possibility that Ang II stimulation raised PFKP expression, and led to facilitate glycolysis and glucose uptake. Namely, Ang II might not only induce aldosterone synthesis but also alter glucose metabolism. We speculate that Ang II may also affect the glucose metabolism of other organs that express AT1R including vascular smooth muscle, endothelium, heart, brain, kidney, and adipose tissue [27]. The relationship between aldosterone synthesis and glucose metabolism has been studied in the past. For example, cytochrome P450 oxidase CYP11A1, CYP11B1 and CYP11B2, which are enzymes that play a major role in aldosterone synthesis, are required for the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH) as an electron donor [29]. Although NADPH has been known to be generated in PPP [30] and the expression of the PPP-related protein did not change in this study, the possibility remains that the induction of PFKP and enhanced glucose consumption might affect the production of NADPH. This is due to the fact that the glycolytic pathway and PPP have the common metabolites such as glucose-6-phosphate, fructose-6-phosphate and glyceraldehyde-3-phosphate [30]. Recently, epidermal growth factor receptor-phosphorylated FFKP has been reported to activate phosphatidylinositol 3-kinase/Akt pathway, which results in the induction of glucose transporter 1 (GLUT1) expression [31]. Since GLUT1 is ubiquitously expressed [32], Ang II-mediated glucose uptake increase may be mediated via the FFKP-induced GLUT1 expression.

In summary, we identified PFKP as a novel target gene of Ang II by proteomic analysis. The up-regulation of PFKP was governed by ERK1/2 kinase involved in
classical MAPK signaling. Furthermore, we showed that Ang II stimulation raised the amount of glucose uptake in H295R cells. This observation suggested that the treatment of cells with Ang II altered glucose metabolism in adrenal cells. Therefore, we considered that it was necessary to investigate the transition of metabolite fluxes derived from glucose stimulated by Ang II.
