ABSTRACT

We analyse the anisotropic clustering of the Sloan Digital Sky Survey-IV Extended Baryon Oscillation Spectroscopic Survey (eBOSS) Luminous Red Galaxy Data Release 14 (DR14) sample combined with Baryon Oscillation Spectroscopic Survey (BOSS) CMASS sample of galaxies in the redshift range $0.6 < z < 1.0$, which consists of 80 118 galaxies from eBOSS and 46 439 galaxies from the BOSS-CMASS sample. The eBOSS-CMASS Luminous Red Galaxy sample has a sky coverage of 1844 deg$^2$, with an effective volume of 0.9 Gpc$^3$. The analysis was made in configuration space using a Legendre multipole expansion. The Redshift Space Distortion signal is modelled as a combination of the Convolution Lagrangian Perturbation Model and the Gaussian Streaming Model. We constrain the logarithmic growth of structure times the amplitude of dark matter density fluctuations, $f(z_{\text{eff}}) \sigma_8(z_{\text{eff}}) = 0.454 \pm 0.134$, and the Alcock-Paczynski dilation scales which constraints the angular diameter distance $D_A(z_{\text{eff}}) = 1466.5 \pm 133.2(r_s/r_{\text{fid}})$ and $H(z_{\text{eff}}) = 105.8 \pm 15.7(r_s^{\text{fid}}/r_s)\text{km s}^{-1}\text{Mpc}^{-1}$, where $r_s$ is the sound horizon at the end of the baryon drag epoch and $r_{\text{fid}}$ its value in the fiducial cosmology at an effective redshift $z_{\text{eff}} = 0.72$. These results are in full agreement with the current Λ-Cold Dark Matter (Λ-CDM) cosmological model inferred from Planck measurements. This study is the first eBOSS LRG full-shape analysis i.e. including Redshift Space Distortions simultaneously with the Alcock-Paczynski effect and the Baryon Acoustic Oscillation scale.

Key words: surveys – dark energy – large-scale structure of Universe.

1 INTRODUCTION

The standard cosmological model (Λ-CDM) accurately describes most observations. However, the acceleration of the expansion of our Universe requires the existence of a dominating source of exotic energy, i.e. the Dark Energy. This energy remains undetected to this day, which has led to many searches for an alternative explanation. One possibility is to modify the geometric part of Einstein’s equations, which corresponds to changing the General Relativity (hereafter GR) equations rather than invoking a new component in the stress–energy tensor. A common modification to GR is the addition of a cosmological constant, Λ, coupled to the metric. However, it is not possible to distinguish between Λ and a specific case of Dark Energy with a constant equation of state $w = -1$.

Another way to reproduce cosmological observations is to modify the gravity model. Various alternative gravitational models have been studied during the past 50 yr which can be grouped in different families. Extra-field theories, such as $f(R)$ (Sotiriou & Faraoni 2010), Tensor-Scalar theories, extra-dimension theories, such as DGP (Fang et al. 2008), braneworld, and string gravity models, and higher order theories such as the Galileons model (Joyce et al. 2015) are some of them.

All modified gravity models must recover the GR results at the local scale (i.e. for high density) where GR has been strongly tested; this is generally solved by invoking screening mechanisms. Therefore, any modification has to appear in the context of weak
gravity and large scales; this is the reason why cosmology, and more particularly Large-Scale Structures (LSS) observations, is the appropriate framework for this study.

Cosmological constraints on the theory of gravity are primarily produced from LSS observations, the most important of these being Supernovae (Riess et al. 1998; Perlmutter et al. 1999), Baryon Acoustic Oscillations (BAOs; Eisenstein et al. 2005; Alam et al. 2017a) and weak lensing (Sheldon et al. 2004), and from the early Universe through Cosmic Microwave Background observations, when the density contrast was of the order of $\sim 10^{-5}$ (Planck Collaboration XIII 2016).

Large-scale peculiar velocities, combined with standard clustering, are a unique framework to distinguish between the various models of gravity. However, obtaining precise relative velocity measurements at large scales ($>10 h^{-1}$ Mpc) is challenging. The Kinetic Sunyaev–Zel’dovich effect is a possibility (Mueller et al. 2014) but requires measurements of massive galaxy clusters with high precision on the SZ signal estimation. Conversely, we can directly use the imprint of these velocities on the redshift measurement through the Redshift Space Distortions (RSD) in the anisotropic correlation function of galaxies (or other tracers of the dark matter) (Kaiser 1987; Hamilton 1992; Cole, Fisher & Weinberg 1995; Peacock et al. 2001; Cabrè & Gaztañaga 2009; Alam et al. 2015; Satpathy et al. 2017; Zarrouk et al. 2018). The measured redshift is the sum of the Hubble flow, the Doppler effect due to the peculiar velocities of the observer, and the observed galaxies, and a small contribution from gravitational redshift. If the peculiar velocities are randomly distributed (i.e. from satellite galaxies inside clusters), then they only contribute as a noise. They are, however, correlated with the density field, revealing cosmological information, in particular allowing us to distinguish between dark energy models or deviations from GR. The Redshift Distortion introduces anisotropies in the galaxy–galaxy two-point correlation function, particularly if we stack the information around overdensities, where these tracers live. Performing an anisotropic study, i.e. using the angle with respect to the line of sight as a statistical breakdown, we can detect the coherent deformations of the 3D two-point correlation function predicted by the Kaiser (1987) effect.

BAO and supernova measurements are constraints on the expansion history of the Universe. However, it has been shown that an appropriate choice of the equation of state $w(a)$ can allow different cosmological models to have the same expansion history (Linder 2005). In order to break this degeneracy one can complement expansion history observations with the clustering history of the structures through the measurement of the linear growth rate:

$$f(a) = \frac{d \ln D(a)}{d \ln a},$$

where $D(a)$ is the linear growth factor as a function of the scale factor $a$, and it quantifies the degree of structure at that time. In this paper we extend the growth rate $f$ measurement from previous surveys to an effective redshift of $z = 0.72$ using the Luminous Red Galaxies (LRGs) sample from the extended Baryon Oscillation Spectroscopic Survey (eBOSS; Dawson et al. 2016).

The paper is organized as follows: Section 2 presents the data, Section 3 describes the mock catalogues used for the estimation of the covariance matrix and for our systematics checks. Section 4 presents the modelling of the RSD signal as well as the parametrization used for the Alcock-Paczynski (AP) test. Section 5 describes the methodology followed in our analysis. Section 6 presents our analysis, using mock catalogues, of the systematic effects associated with our methodology. The results for the eBOSS–CMASS sample are presented in Section 7. Finally, the cosmological implications of this work are reviewed in Section 8.

2 DATA

Our sample of spectroscopic data were collected during the first 2 yr of eBOSS (Dawson et al. 2016), which is the cosmological component of the fourth generation of the Sloan Digital Sky Survey (SDSS-IV; Blanton et al. 2017). All of our spectra were obtained by the Sloan 2.5 m telescope using two multiobject spectrographs (Smee et al. 2013) at Apache Point Observatory in New Mexico, USA (Gunn et al. 2006). All of these data belong to the SDSS Data Release 14 (Abolfathi et al. 2017), of which we analyse the Luminous Red Galaxies (LRG) Sample. The LRG targets were selected based on updated photometric data from SDSS I/II/III imaging (Fukugita et al. 1996; Gunn et al. 1998) for which the calibration of the photometric data was updated following the procedure presented in Schlafly & Finkbeiner (2011). The target selection process also used infrared photometry data from the Wide-Field Infrared Survey Explorer (WISE; Wright et al. 2010). The WISE satellite observed the entire sky using four infrared channels, respectively, centred at 3.4 $\mu$m (W1), 4.6 $\mu$m (W2), 12 $\mu$m (W3), and 22 $\mu$m (W4). The eBOSS LRG sample uses the W1 and W2 bands. Given that stars have different properties than galaxies in infrared (particularly due to the galactic dust), the WISE data allow us to reduce the stellar contamination, it is also useful for extending the redshift range with respect to BOSS. The target selection follows the algorithm described in Prakash et al. (2016).

2.1 eBOSS–CMASS sample

Our eBOSS DR14 LRG sample includes data of the first 2 yr of the eBOSS program combined with the BOSS CMASS data (Alam et al. 2017a) which overlaps with the eBOSS footprint in a redshift range of $0.6 < z < 1.0$. This approach allows construction of a more complete sample without decreasing the median redshift.

The eBOSS–CMASS sample is composed of 80 118 galaxies from eBOSS and 46 439 from CMASS, yielding a total of 126 557 galaxies. The numbers separated by Galactic hemisphere are listed in Table 1. The sky coverage in the North Galactic Cap (hereafter NGC) is 1011.15 and 788.09 deg$^2$ in the South Galactic Cap (hereafter SGC), giving a total solid angle of 1844.0 deg$^2$. The effective volume of eBOSS is 0.618 Gpc$^3$ which increases up to 0.9 Gpc$^3$ when considering the eBOSS–CMASS sample.

Fig. 1 shows the number density of the sample as a function of redshift for both hemispheres, the solid blue lines correspond to the NGC and the dashed red lines to the SGC; the dashed vertical lines indicate the redshift cuts applied for our analysis. The median redshift of the sample is $z = 0.72$, which is represented by the vertical dotted line.

2.2 Footprint and masks

The left-hand and right-hand panels of Fig. 2 display the sky coverage of the galaxy sample for the NGC and SGC, respectively, where the colour scale indicates the targeting completeness defined as:

$$C = \frac{N_{gal} + N_{qso} + N_{dat} + N_{cp} + N_{fail}}{N_{target}},$$

with $N_{gal}$ being the number of galaxies, $N_{qso}$ being the number of quasars, $N_{dat}$ being the number of target sources, $N_{cp}$ being the number of complete pointings, and $N_{fail}$ being the number of failure pointings.
Table 1. Characteristics of the LRG data catalogues used. The left-hand panel corresponds to the BOSS CMASS sample from DR12, the right to the eBOSS LRG DR14 sample. \( N_{\text{star}} \) and \( N_{\text{qso}} \) are the number of objects whose spectra were determined to be stars or quasars instead of LRGs. \( N_{\text{fail}} \) is the number of objects whose redshift measurement was not reliable, and \( N_{\text{np}} \) the number of objects without spectra due to close pair effects. The last line reports the number of galaxies and the effective volume of our final sample, which is a combination of the CMASS and eBOSS samples.

| Catalogue | Area (deg^2) | Total redshifts |
|-----------|-------------|-----------------|
| CMASS–BOSS NGC | 1011.15 | 26 149 – – – – – – |
| CMASS–BOSS SGC | 788.09 | 20 290 – – – – – – |
| eBOSS NGC | 45 826 | 2897 18 2263 4957 1033.4 0.356 |
| eBOSS SGC | 34 292 | 4273 18 1687 4366 811.6 0.262 |
| Total | 80 118 | 7170 36 3950 9323 1844.0 0.618 |
| eBOSS-CMASS | 126 557 | – – – – – – 0.900 |

where

(i) \( N_{\text{gal}} \) is the number of galaxies with good quality eBOSS spectra.

(ii) \( N_{\text{cp}} \) is the number of galaxies without spectra due to the fibre collision effect. Two fibres cannot be closer than 62 arcsec on a given plate.

(iii) \( N_{\text{star}} \) denotes the number of observed objects which are spectroscopically confirmed to be stars.

(iv) \( N_{\text{fail}} \) denotes the number of objects for whom the measured spectra lacks sufficient qualities to provide a confident redshift measurement.

The targeting completeness is computed by sector, and the mean completeness is 96.3 per cent (where the NGC has an average completeness of 95.9 per cent and the SGC 96.9 per cent). We only use data from regions with a completeness higher than 0.5 (this value is smaller than the completeness used in BOSS).

Certain areas in the sky have to be excluded from the final data sample. The maps of these excluded regions are known as veto masks and have to be removed from our random catalogues as well. The veto masks used in eBOSS were:

(i) The collision priority veto mask that excludes regions that are closer than 62 arcsec from an already observed target, as any object inside this radius would not be observed due to fibre collision.

(ii) The bright veto mask which excludes regions around stars that are part of the Tycho catalogue (Høg et al. 2000) with Tycho BT magnitudes larger than 6 and lower than 11.5. The excluded radius is magnitude-dependent and it goes from 0.8 to 3.4 arcmin. An additional mask excludes regions around bright galaxies and other objects (Rykoff et al. 2014); it is also magnitude-dependent and goes from a radius of 0.1 to 1.5 arcmin.

(iii) The bad fields veto mask excludes regions of the sky with bad photometry. If the local sky is badly determined (as occasionally happens in regions with complex backgrounds), the core of an object can be strongly negative.

(iv) The extinction mask excludes regions where the Galactic extinction is such that \( E(B - V) > 0.15 \) or where the seeing full width at half-maximum (FWHM) is larger than 2.3, 2.1, and 2.0 arcsec in \( g, r, \) and \( i \) bands, respectively.

(v) The centre focal plane mask excludes LRG targets that lie within 92 arcsec of the centre of the telescope focal plane, where a centre post holds the plate and prevents fibres from being assigned.
The total masked area is 12.3 per cent for the NGC and 18.2 per cent for the SGC.

### 2.3 Catalogue for LSS analysis

Two data catalogues that differ in their treatment of the photometric systematics and of spectroscopic incompleteness were used to create the sample for our study. The first is a BOSS-like catalogue where traditional weighting schemes are applied, described in Ross et al. (2017), to the data. The second is denoted as the 'official catalogue', and it was used in Bautista et al. (2018) for performing the BAO analysis. Here some improvements with respect to previous analysis were implemented: the forward modelling of the randoms for the spectroscopic incompleteness and the multilinear regression and subsampling of the randoms for the photometric systematics.

In this section, we briefly review both methodologies, first describing the different treatments of the photometric systematics, and then the procedures used for dealing with the redshift incompleteness. Finally, we summarize the weights applied to the data for both cases and also the subsampling techniques used in the random catalogues in each case.

#### 2.3.1 Correcting for photometric systematics

Here we will give a brief description of the two methodologies for correcting photometric systematics:

(i) Iterative method ('BOSS-like') was developed in Ross et al. (2017). The basic idea is to include the systematics in an iterative way and estimate at each step the associated weights. For the eBOSS LRG sample, we studied the correlation of the mean density as a function of seven potential observational systematics related with SDSS photometry: stellar density, $i$-band depth, $z$-band sky flux, $z$-FWHM, and $r$-band extinction.\(^1\) We followed the iterative method starting with the main systematics reported in previous works. Fig. 3 displays the mean density of data, $N_{\text{gal}}$, normalized by the random number density, $N_{\text{ran}}$, as a function of six of the seven systematics considered in the analysis before and after corrections. The most significant weights are those due to stellar density ($w_{\text{star}}$), $r$-band extinction ($w_{\text{ext}}$), airmass ($w_{\text{air}}$), and $z$-band sky flux ($w_{\text{sky}}$). The systematics related with the WISE maps did not have any strong correlation requiring correction, thus we decided not to include them in the weight estimation. We calculate a weight for each galaxy that takes into account a linear relationship for each potential systematic.

$$w(\text{sys}) = \frac{1}{m x + b}. \quad (3)$$

The total systematic weight $w_{\text{sys tot}}$ is defined as

$$w_{\text{SYS TOT}} = w_{\text{star}} w_{\text{ext}} w_{\text{air}} w_{\text{sky}} \quad (4)$$

(ii) Multiregression method: We followed the same methodology presented in Bautista et al. (2018), where the correlation between systematic maps and density were computed using a multilinear regression of the seven systematic maps instead of the iterative method. The advantage of this method is that it does not assume

\(^1\)Additionally we explored two additional maps derived from WISE photometry: one for the median number of single-exposure frames per pixel in the WISE W1 band (denoted as WISE W1 Cov Med) and the median of accumulated flux per pixel in the WISE W1 band (denoted by WISE W1 Med).

---

Figure 3. We show the mean density of data, $N_{\text{gal}}$, normalized by the random number density, $N_{\text{ran}}$ as a function of six of the nine systematics considered in the analysis. The most significant weights were those due to stellar density ($w_{\text{star}}$), $r$-band extinction ($w_{\text{ext}}$), airmass ($w_{\text{air}}$), and $z$-band sky flux ($w_{\text{sky}}$).
the systematics are independent, as does the iterative method. Additionally, in the official catalogues, instead of using weights associated with galaxies, the randoms are subsampled following the correlation found with the multiregression method; the subsampling of the randoms or the weighting scheme of the galaxies should yield the same results; the main differences observed in the catalogues should be derived uniquely from the Iterative/Multilinear regression methodologies.

2.3.2 Correcting for spectroscopic incompleteness

Previous analyses on the eBOSS LRG sample reported that fluctuations in the (S/N) significantly affect the probability of obtaining a confident redshift (see fig. 5 of Bautista et al. 2018). Additionally, the probability of obtaining a confident redshift varies across the focal plane, decreasing near the edges (see fig. 6 of Bautista et al. 2018). We define the failure rate as:

\[
\eta = \frac{N_{\text{gal}}}{N_{\text{gal}} + N_{\text{fail}}}.
\]

where the failure rate in eBOSS LRGs sample is 10 per cent, which is significantly higher than previous surveys; for example, in BOSS the failure rate was only 1.8 per cent (This is due to eBOSS targeting fainter galaxies than BOSS).

2.3.3 Data weights

We now specify the weights applied for each catalogue and the randoms treatment.

(i) \(w_{\text{Syst.}}\). As described previously, these weights account for the fluctuations of the observational conditions that can impact the clustering signal. For the BOSS-like method these weights are computed as described in the iterative method.

(ii) \(w_{\text{FKP}}\). These weights are used for both set of catalogues. They serve to optimize clustering signal-to-noise ratio for a survey with density varying with respect to the redshift. Also known as FKP weights (Feldman, Kaiser & Peacock 1994), they are defined as:

\[
w_{\text{FKP}} = \frac{1}{1 + \bar{n}(z)P_{0}},
\]

where \(\bar{n}(z)\) is the average comoving density of galaxies as a function of redshift and \(P_0\) is the value of the power spectrum at scales relevant for our study (\(k = 0.14h\ Mpc^{-1}\)). For the eBOSS LRG sample we adopt a value of \(P_0 = 10^3 h^{-3} \ Mpc^3\), which is the same value used in the final BOSS CMASS clustering measurements.

(iii) \(w_{\text{CP}}\). This weight accounts for the fibre collisions and is used for both catalogues. Targets missed due to fibre collisions do not happen randomly on the sky; they are more likely to occur in overdense regions. For mitigating this effect we followed the up-weighting technique described previously.

(iv) \(w_{\text{NOZ}}\). This weight accounts for the redshift failures. For the BOSS-like method this weight is computed for each galaxy following the up-weighting technique described in the previous section.

3 MOCKS

We use three different sets of mock catalogues in our analysis. The first is a collection of 1000 Quick Particle Mesh (QPM) mocks (White, Tinker & McBride 2014), which will be used for computing the covariance matrices and for doing several systematic tests. The second one is a set of 1000 Effective Zeldovich approximation method (EZ) mocks Chuang et al. (2015), that are used to test
parameters tuning to the DR14 eBOSS LRG sample in Zhai et al. described in Tinker et al. (2012) but taking into account the HOD haloes with galaxies following the five-parameter method. Occupation Distribution (HOD) framework is adopted for populating haloes with galaxies following the five-parameter method described in Tinker et al. (2012) but taking into account the HOD parameters tuning to the DR14 eBOSS LRG sample in Zhai et al. (2017).

The same boxes were used for generating NGC and SGC mocks, thus there should be a small correlation between them (particularly in the large modes). In order to mitigate this effect, we combined mocks produced by different realizations of the NGC and the SGC. The mask that we applied to the mocks will be described in Section 2.2.

Our QPM mocks are needed for two reasons: to compute an estimate of the covariance matrix and to test our methodology. Fig. 5 shows the mean of the mocks compared with the data; the solid lines represent the mean of the mocks correlation function and the blue dots the data correlation function multipoles with their associated error bars. There is a good agreement between the data and the mocks for scales larger than 30 $h^{-1}$ Mpc; at smaller radii a mismatch appears, which might be related to the resolution of the mocks.

3.1 QPM mock catalogues

We use 1000 realizations of QPM mocks using the following cosmology $\Omega_M = 0.29$, $h = 0.7$, and $\Omega_b h^2 = 0.02247$. A Halo Occupation Distribution (HOD) framework is adopted for populating haloes with galaxies following the five-parameter method described in Tinker et al. (2012) but taking into account the HOD parameters tuning to the DR14 eBOSS LRG sample in Zhai et al. (2017).

3.2 EZ mock catalogues

EZ simulations are light-cone mock catalogues created following the Effective Zeldovich methodology described in Chuang et al. (2015). In order to construct the eBOSS + CMASS sample, the CMASS and eBOSS mocks are calibrated and generated separately and then combined. The CMASS mocks are constructed in four redshift bins: (0.55, 0.65), (0.65, 0.7), (0.7, 0.8), and (0.8, 1.0025), while the eBOSS mocks are constructed at five redshift bins: (0.55, 0.65), (0.65, 0.7), (0.7, 0.8), (0.8, 0.9), and (0.9, 1.05). The fiducial cosmology is a flat $\Lambda$CDM model with $\Omega_M = 0.307115$, $h = 0.6777$, $\sigma_8 = 0.8225$, $\Omega_b = 0.048206$, and $n_s = 0.9611$. We will use these mocks to test the variance of the fitting methodology.

3.3 N-series cut sky mocks

Our N-series cut sky mock library contains 84 mocks generated with N-body simulations that where done using GADGET2 (Springel 2005). Our mocks have the angular and radial mask of BOSS NGC DR12 based on simulations with 2048$^3$ particles in a volume of $(2.6 h^{-1}$ Gpc)$^3$ corresponding to resolution particle mass about $1.5 \times 10^{13} M_{\odot} h^{-1}$. We used these mock catalogues to test the theoretical systematics related to our modelling methodology. The N-Series cosmology is $\Omega_M = 0.286$, $h = 0.7$, $\Omega_b = 0.047$, $\sigma_8 = 0.820$, and $n_s = 0.96$.

4 MODELLING REDSHIFT SPACE DISTORTIONS

In order to model the different multipoles of the two-point correlation function, we use the combined Convolutional Lagrangian Perturbation Theory (CLPT) and Gaussian Streaming RSD (CLPT-GSRSRD) formalism, developed by Wang, Reid & White (2014), Reid & White (2011), and Carlson, Reid & White (2013). In this section we briefly describe this theoretical framework.

4.1 CLPT

CLPT provides a non-perturbative resummation of Lagrangian perturbation to the two-point statistic in real space for biased tracers. The starting point for the Lagrangian framework is the relation between the Lagrangian coordinates $\vec{q}$ that are related to the Eulerian coordinates $\vec{x}$ as:

$$\vec{x}(\vec{q}, t) = \vec{q} + \Psi(\vec{q}, t),$$

where $\Psi(\vec{q}, t)$ is the displacement field at each time $t$. The two-point correlation function is expanded in its Lagrangian coordinates considering the tracer $X$, in our case the LRGs, to be locally biased with respect to the initially Cold Dark Matter overdensity $\delta(\vec{q})$. The expansion is performed over different orders of the Lagrangian bias function $F[\delta(\vec{q})]$, defined as:

$$1 + \delta_X(\vec{q}, t) = F[\delta(\vec{q})].$$

The Eulerian contrast density field is computed convolving with the displacements:

$$1 + \delta_X(\vec{x}) = \int \frac{d^3k}{(2\pi)^3} e^{i k \cdot (\vec{x} - \vec{x}(\vec{q}, t))} F[\delta(\vec{q})].$$
Assuming that the expectation value of the nth derivative of the Lagrangian bias function $F$ is given by:

$$\langle F^n \rangle = \int \frac{d\delta}{\sqrt{2\pi\sigma}} e^{-\delta^2/2\sigma^2} d^{3} q F,$$

the two-point correlation function is obtained by evaluating the expression $\xi_2(r) = \langle \delta x(\delta x + \delta y) \rangle$ corresponding to equation (19) of Carlston et al. (2013) and which can be simplified using the bias expansion as in their equation (43):

$$1 + \xi_2(r) = \int d^{3} q M(\vec{r}, \vec{q}),$$

where $M(\vec{r}, \vec{q})$ is the kernel of convolution taking into account the displacements and bias expansion up to its second derivative term. The bias derivative terms are computed using a linear power spectrum (LPS). The LPS that we used was computed using the code CAMB (Lewis, Challinor & Lasenby 2000) for a fixed cosmology described as the fiducial cosmology of our analysis.

As we are interested in studying RSD, we also must model the peculiar velocity’s effect on the clustering statistic. GLPT can compute the pairwise velocity distribution $\vec{v}_{12}$ and the pairwise velocity dispersion $\sigma_{12}$. This calculation is done following the formalism of Wang et al. (2014) which is similar to the one described above but modifying the kernel to take into account the velocities rather than the density:

$$\vec{v}_{12}(r) = (1 + \xi(\vec{r}))^{-1} \int M_{1}(\vec{r}, \vec{q}) d^{3} q,$$

and

$$\sigma_{12}(r) = (1 + \xi(\vec{r}))^{-1} \int M_{2}(\vec{r}, \vec{q}) d^{3} q.$$  

The kernels $M_{1,2}(\vec{r}, \vec{q})$ also depend on the first two derivatives of the Lagrangian bias ($F'$ and $F''$), which are free parameters, in addition to the growth factor $f$, for our model. Hereafter we eliminate the brackets for the Lagrangian bias terms to have a less cumbersome notation in the following sections.

### 4.2 CLPT-GSRS

While CLPT generates more accurate multipoles than the Lagrangian Resummation Theory (LRT) from Matsubara (2008) and the linear theory, we still require better performance to study the smaller scales of our quadrupoles. This represents an issue that is particularly important when doing RSD measurements as the peculiar velocities are generated by interactions that occur on the scales of clusters of galaxies.

In order to achieve the required precision, we map the real space CLPT models of the two-point statistics into redshift space following the Gaussian Streaming Model (GSM). This formalism was proposed by Reid & White (2011). Here, the pairwise velocity distribution of tracers is assumed to have a Gaussian distribution that is dependent on both the separation of tracers $r$ and the angle between their separation vector and the line-of-sight $\mu$.

The methodology of using CLPT to model the necessary inputs of a GSM was implemented by Wang et al. (2014). Its predictions are computed via the following integral:

$$1 + \xi(\vec{r}, \vec{r}) = \int \frac{1}{\sqrt{2\pi(\sigma_{12}(r, \mu) + \sigma_{\phi G})}} [1 + \xi(r)] \times \exp \left[-\frac{|\vec{r} - \vec{r} - \mu\vec{v}_{12}(r, \mu)|^2}{2(\sigma_{12}^2(r, \mu) + \sigma_{\phi G})} \right] dy,$$

where, as stated, $\xi(r)$, $v_{12}(r)$, and $\sigma_{12}(r)$ are computed from CLPT. Reid & White (2011) demonstrated that GSM can predict accuracies of $\approx 2$ per cent when DM haloes are used as tracers. However, not all LRGs are central halo galaxies; approximately 20 per cent of them are satellite galaxies with a peculiar velocity respect to their host halo. Therefore, we need to consider a contribution to the velocity dispersion due to the Fingers of God (FoG) effects on non-linear scales. We have addressed this point by adding the $\sigma_{\phi G}$ parameter to equation (14).

To summarize, given a fiducial cosmology, our model has four free parameters [$f$, $F'$, $F''$, $\sigma_{\phi G}$]. The cosmology determines the LPS used in the model. The following subsection describes how we include variations of the cosmological parameters around the fiducial values using the Alcock–Paczynski Test.

### 4.3 Including the Alcock–Paczynski effect

We described above the model for the RSD signal given a fixed fiducial cosmology that determines the LPS to be used. However, we can extract additional information by measuring the galaxy clustering along the line of sight and perpendicular to the line of sight, and we can extract geometrical information via the Alcock–Paczynski (AP) test (Alcock & Paczynski 1979). In this work, for extracting AP information, we use the parametrization described in Xu et al. (2012), Vargas-Magaña et al. (2014), and Anderson et al. (2014), which derives measurements of the isotropic dilation of the coordinates parametrized by $\alpha$ and the anisotropic warping of the coordinates parametrized by $\epsilon$:2 We remind the connection with the other parametrization, that we will further use for comparison with previous works, is given by:

$$\alpha = \alpha_{\perp}^2 \alpha_{||}^{1/3},$$

$$1 + \epsilon = \left(\frac{\alpha_{||}}{\alpha_{\perp}}\right)^{1/3},$$

where $\alpha_{\perp}$ and $\alpha_{||}$ are defined in terms of dilation in the transverse and line-of-sight directions.

### 5 METHODOLOGY

#### 5.1 Fiducial cosmology

Our analysis is performed using the following fiducial cosmology:

- $\Omega_M = 0.31$,
- $\Omega_k = 0.69$,
- $\Omega_k = 0$,
- $\Omega_b h^2 = 0.022$,
- $\Omega_c h^2 = 0.0064$,
- $w = -1$,
- $w_s = 0$,
- $h = 0.676$,
- $n_s = 0.97$,
- $\sigma_8 = 0.8$.

2Note that $\alpha = 1$ and $\epsilon = 0$ for the mocks, if we use their natural cosmology as the fiducial cosmology for the analysis.
This fiducial cosmology is different from the ones used to compute the mocks; this additional bias in our methodology has to be considered. This extra bias will be defined in Section 6.

5.2 2PCF estimator

The following section will describe the methodology used to compute the two-point clustering statistics of the DR14 LRG sample described in Section 2.

We are interested in constraining RSD parameters. Therefore, we must study the clustering of galaxies in two directions: the one parallel to the LOS, where peculiar velocities of infalling galaxies generate RSD, and its perpendicular direction, where no distortion occurs. We decompose the vector \( \mathbf{r} \), which represents the distance between two galaxies, into two components: \( r_{||} \) parallel to the LOS and \( r_{\perp} \) that is perpendicular to it:

\[
 r^2 = r_{||}^2 + r_{\perp}^2. \tag{16}
\]

Let \( \theta \) denote the angle between the galaxy pair separation and the LOS direction, and let \( \mu \) be defined as \( \mu = \cos \theta \). We then have the relation:

\[
 \mu^2 = \cos^2 \theta = \frac{r_{\perp}^2}{r^2}, \tag{17}
\]

and our two direction parameters will be \([r, \mu]\).

The 2D-correlation function \( \xi(r, \mu) \) is computed using the Landy–Szalay estimator (Landy & Szalay 1993):

\[
 \xi(r, \mu) = \frac{DD(r, \mu) - 2DR(r, \mu) + RR(r, \mu)}{RR(r, \mu)}, \tag{18}
\]

where \( DD(r, \mu), RR(r, \mu) \), and \( DR(r, \mu) \) are the number of pairs of galaxies which are separated by a radial separation \( r \) and angular separation \( \mu \). The three symbols represent the data–data, random–random, and data–random pairs, respectively.

The multipoles are Legendre moments of the 2D-correlation function \( \xi(r, \mu) \), and can be computed using the following equation:

\[
 \xi_i(r) = \frac{2\ell + 1}{4\pi} \int_{-1}^{1} \mathrm{d}\mu \xi(r, \mu) L_{\ell}(\mu), \tag{19}
\]

where \( L_{\ell}(\mu) \) is the \( \ell \)-th order Legendre polynomial.

We will focus primarily on the monopole, the quadrupole, and the hexadecapole (\( \ell = 0, \ell = 2, \) and \( \ell = 4 \)).

The pair-counts were computed using the public code CUTE (Alonso 2012). However, there are three corrections to be considered when using the LS equation (18):

(i) The number of galaxies in the Data catalogues \( N_D \) is approximately 50 times smaller than the ones in our random catalogues \( N_m \). Therefore the Random and Data pairs should be compared as

\[
 \frac{DD(r, \mu)}{RR(r, \mu)} \times \frac{N_m(N_m - 1)}{2} \times \frac{2}{N_D(N_D - 1)}.
\]

(ii) The number of galaxies in the SGC \( N_{D,3} \) is smaller than those in the NGC \( N_{D, N} \). Therefore the total number of pairs should be added as:

\[
 \frac{DD_{\ell}(r, \mu) + DD_{\ell}(r, \mu)}{N_{D, N}(N_{D, N} - 1) + N_{D,3}(N_{D,3} - 1)}.
\]

(iii) Each galaxy has a particular weight \( w_i \) as described in Section 2. Hence, the total number of galaxies in any catalogue is weighted as

\[
 N^w = \sum w_i.
\]

5.3 Fitting

Unless stated otherwise, we will be using 13 bins of \( 8 h^{-1} \) Mpc in width, in the interval between \([28 h^{-1} \text{Mpc}, 124 h^{-1} \text{Mpc}]\). Given that we will be working with either the first two non-zero multipoles or the first three (depending on the test), the analysis will have a total of either 26 or 39 bins.

We will now compare our measured two-point statistics with those predicted by our model and try to find the best-fitting model parameters.

In order to find identify best-fitting parameters, we minimize the \( \chi^2 \) function,

\[
 \chi^2 = (\bar{m} - \tilde{d})^T C^{-1} (\bar{m} - \tilde{d}), \tag{20}
\]

where \( \bar{m} \) is the vector formed by the model predictions, and \( \tilde{d} \) is the equivalent vector observed from our data. Examining equation (20) reveals that the smaller the value of \( \chi^2 \), the more similar \( \bar{m} \) is to \( \tilde{d} \).

The sample covariance is defined as:

\[
 C_{ij} = \sum_{m=1}^{N_{\text{mocks}}} (\xi^m_i - \bar{\xi}_i)(\xi^m_j - \bar{\xi}_j), \tag{21}
\]

where \( N_{\text{mocks}} \) is the number of mocks, and \( \bar{\xi}_i \) is the average of the \( i \)-th bin.

We scale the inverse sample covariance matrix, \( C^{-1} \), using equation (17) of Hartlap, Simon & Schneider (2007):

\[
 C^{-1} = C^{-1}_{\text{mocks}} - \frac{N_{\text{mocks}} - 2}{N_{\text{mocks}} - 1}. \tag{22}
\]

This procedure corrects for the fact that the matrix in equation (21) is a biased estimate of the true inverse covariance matrix \( C^{-1} \).

Fig. 6 shows the covariance and correlation matrix computed from 1000 QPM mocks. Most of our error arises from the elements on the diagonal (variance of a given bin), but there is also a significant contribution coming from elements outside of the diagonal (covariance between different bins).

In order to identify the best-fitting parameters, we minimize the \( \chi^2 \) function. The minimization of the \( \chi^2 \) is done using the Powell algorithm (Press et al. 2002). This algorithm will find a unique solution if the parameter space is Gaussian, which should be a fair assumption when fitting our mocks. This method is adequate for our work as it does not require us to compute the gradient of the CLPT-GSRD model with respect to the model parameters, which would be challenging. Due to the nature of the algorithm it is not necessary to specify any prior, just some starting points, if our assumption about the parameter space being somewhat Gaussian is correct then any starting point should work fine and one that is close to the Best Fit should reduce the running time.

The estimate of the errors on our fits will be computed using MCMC chains, but we will only do this analysis for our data sets (Section 7) and not for the mocks.

6 TESTING FOR SYSTEMATIC UNCERTAINTIES

6.1 Testing accuracy of GSRD hexadecapole model with high-resolution simulations

This section is dedicated to testing the performance of the methodology developed in Section 5. Here, we will use the N-Series CutSky mocks described in Section 3 to check the reliability of the CLPT model with regards to recovering the cosmological parameters. These high resolution mocks are built with the BOSS–CMASS
properties that allow us to study the accuracy of the model. We will run our fitting methodology on these high-fidelity mocks in order to test if their fiducial parameters can be recovered. The N-Series CutSky mocks have been used previously in the literature for testing the monopole- and quadrupole-only methodologies.

We fit our N-series CutSky mocks twice, the first using only the monopole and the quadrupole, and the second including the hexadecapole. The fits are done following the methodology described in Section 5.3, but here we will be using 21 bins of $5\, h^{-1}\text{Mpc}$ in width, in the interval between $[27.5\, h^{-1}\text{Mpc}, 127.5\, h^{-1}\text{Mpc}]$. We decided to choose a smaller bin-size to facilitate comparisons with other previous results. The sample covariance matrix used to perform these fits is computed using the QPM-BOSS CMASS sample re-scaled to match the mocks volume, and provides our error estimate (the covariance matrix obtained from N-Series mocks would be quite noisy given the limited number of realizations available). The pair-counts of our mocks were computed using the mocks cosmology to transform angular positions and redshifts into comoving coordinates. To be consistent, the CLPT-GSRSD input template was also computed using the cosmology of the mocks.

The expected values of the linear growth rate of $f$ ($f_{\text{exp}}$) are reported in Table 2 for the natural cosmology of the mocks. We define the bias of the growth factor estimation by as:

$$b_f = \langle f_{\text{measured}} \rangle - f_{\text{exp}}.$$

We use the measurement of the Eulerian bias $b = 2.3$ performed by Zhai et al. (2017) as reference. This estimate was computed using our same sample with the addition of an HOD model.

The left-hand panel of Fig. 7 shows the mean of the multipoles; the error bars are the diagonal terms of the covariance matrix divided by $1/\sqrt{N_{\text{mocks}}}$. The different colours (and line-styles) represent the best-fitting model for the mean of the mocks using the fiducial range at different minimum scales of the fits when the cuts are applied to all multipoles.

The model using the hexadecapole fitted at the full range (blue lines) does not match the hexadecapole of the mean of the mocks accurately at any scale, this can be seen in the corresponding residual plot (bottom panel of the figure) where the value of the residuals is close to 50 per cent of the value of the model, this is very large when compared to the residuals of the monopole and quadrupole that are around 10 per cent and 2 per cent, respectively (second and third panels of the figure). Increasing the minimum range of the fit mostly affects the quadrupole at large scales and has little effect on the monopole and hexadecapole at any scale. By comparing the residuals of the quadrupole (third panel of the figure) of the full-range fit and the reduced-range fit we can tell that the full range fits adjusts the quadrupole better (i.e. the blue solid line is a better fit than the green dotted one).

The right-hand panel of Fig. 7 displays a similar exercise to the one in the left panel, except this time we only cut the minimum scale of the hexadecapole while leaving the other two multipoles in the full range. The changes on the quadrupole are now less severe than when varying all multipoles. By looking at the residual plot of the quadrupole (third panel of the figure) we see that the model considering the hexadecapole in the full range (green dash-dotted line) matches the quadrupole slightly better than the model using only the monopole and quadrupole (purple solid line), but it does not improve the other multipoles significantly. It is not clear that including the hexadecapole improves the fits significantly when compared to the monopole and quadrupole only case.

Table 3 reveals that the bias in $f$ is slightly larger when we include the hexadecapole in the full range than when we only use the monopole and the quadrupole ($b_f = 0.005$ compared to $b_f = 0.004$). However, the bias in $\epsilon$ is smaller when the hexadecapole is left out of the fits ($b_\epsilon = 0.002$ compared to $b_\epsilon = 0.0005$). The bias in alpha is the same for both cases ($b_\alpha = 0.001$). The right panel of Fig. 7 shows that the best fit model for both cases are very similar, only showing small differences in the quadrupole at the scales in the range [80,110] $h^{-1}\text{Mpc}$.

Reducing the range for all multipoles (second block of the table) increases the biases in $f$ and $\epsilon$. If by contrast we constrain the range only for the hexadecapole (third block), we reduce the bias in $f$ and $\alpha$ to $b_f = 0.001$ and $b_\alpha < 0.001$, respectively, leaving the bias value for $\epsilon$ unchanged.

In summary, there is no clear preference between the case with the multipoles and just considering monopole and quadrupole. There is a trade-off between the biases in $\epsilon$ and $f$. The smaller bias in $f$ is
Table 2. Expected values of cosmological parameters for the QPM mocks and fiducial cosmology at different redshift ranges/model. The units for \( H(z) \) are \( \text{km s}^{-1}\text{Mpc}^{-1} \) and \( (\text{Mpc}) \) for \( D_A(z) \).

| Model  | \( z \)-range | \( z_{\text{eff}} \) | \( f(z) \) | \( \sigma_8(z) \) | \( f(z)\sigma_8(z) \) | \( H(z) \) | \( D_A(z) \) |
|--------|----------------|-----------------|----------|----------------|----------------|----------------|----------------|
| QPM    | [0.6, 1.0]     | 0.72            | 0.806    | 0.557          | 0.449          | –              | –              |
| Fiducial | [0.6, 1.0]     | 0.72            | 0.819    | 0.550          | 0.450          | 101.94         | 1535           |
| Nseries | [0.43, 0.7]    | 0.5             | 0.740    | 0.637          | 0.471          | –              | –              |

Figure 7. The mean of the mocks is shown as the black line in both plots. The error bars are computed from the re-scaled QPM mocks covariance. The left-hand panel shows the best-fitting models from different lower ranges of the multipoles. In the right-hand panel only the lower range of the hexadecapole is varied. The error plots show the quotient between the best-fitting model and the mean of the mocks. For all cases are residuals in the hexadecapole, the smaller residuals are obtained by the monopole + quadrupole.

Table 3. Results from fitting the mean of N-series Mocks. The expected values for the N-series mocks are \( f(z = 0.5) = 0.740, \alpha = 1.0 \) and \( \epsilon = 0.0 \). The fits are done over bins of \( 5 \, h^{-1} \text{Mpc} \) each so that the full range of each multipole \((27.5h^{-1} \text{Mpc}, 127.5h^{-1} \text{Mpc})\) will have 21 bins.

| Model                  | Range          | \( f' \)         | \( F' \)         | \( f \)         | \( \alpha \)  | \( \epsilon \) | \( \sigma_{\text{FoG}} \) | \( \chi^2/\text{d.o.f} \) |
|------------------------|----------------|-----------------|-----------------|----------------|--------------|--------------|----------------|-----------------|

| \( \xi_0 + \xi_2 + \xi_4 \) with a cut in hexadecapole only | 37.5–127.5     | 1.014           | 1.014           | 0.735          | 1.001        | –0.003      | 2.239          | 84.0/51 = 1.65  |
| \( \xi_0 + \xi_2 + \xi_4 \) | 42.5–127.5     | 1.032           | 1.022           | 0.731          | 0.999        | –0.004      | 0.530          | 78.7/48 = 1.64  |
| \( \xi_0 + \xi_2 + \xi_4 \) | 47.5–127.5     | 1.027           | 3.149           | 0.721          | 0.997        | 1.018       | 70.8/45 = 1.57  |
| \( \xi_0 + \xi_2 + \xi_4 \) | 37.5–127.5     | 1.031           | 1.010           | 1.543          | 0.742        | 1.000       | 2.793          | 86.15/55 = 1.57 |
| \( \xi_0 + \xi_2 + \xi_4 \) | 42.5–127.5     | 1.011           | 1.011           | 1.649          | 0.741        | 1.000       | 2.938          | 86.18/54 = 1.60 |
| \( \xi_0 + \xi_2 + \xi_4 \) | 47.5–127.5     | 1.012           | 1.012           | 1.697          | 0.741        | 1.000       | 2.984          | 86.28/53 = 1.62 |

obtained when using the hexadecapole while the smaller bias in \( \epsilon \) comes from using only the monopole and quadrupole. As there is not a clear trend we will explore the hexadecapoles impact on the LRG sample analysis further.

Fig. 8 displays the model behaviour for variations of the parameters, and is included to explain the different trends observed with mocks when using multipoles up to order \( \ell = 2 \) compared to \( \ell = 4 \). We also indicate the variations in our model predicted by changes of \( \sim 20 \% \) in the input parameters, that correspond to deviations of \( \Delta f = 0.15, \Delta \alpha = 0.2, \) and \( \Delta \epsilon = 0.2 \) around the fiducial cosmology expected value. The error bars were obtained from the diagonal of the mocks covariance matrix. The variations in \( \epsilon \) have a large impact on the predicted hexadecapole at all scales (middle curve), while the variations of the hexadecapole due to variations in the hexadecapole are small (top curve).
on $\alpha$ and $f$ are significantly smaller and of a comparable order of magnitude. This behaviour explains why the fits are driven by $\epsilon$ when the hexadecapole is included. Considering that the error bars between 20 and 60 $h^{-1}$Mpc are smaller, their constraining power is significantly larger.

As stated before, even if our results using the hexadecapole do not show significant biases, Fig. 7 shows that the model obtained using the cosmology of the mocks does not accurately match the mean of the hexadecapole mocks at any scale, in particular at the lower scales that have more weight in the likelihood. This mismatch in the hexadecapole is pushing $\epsilon$ to higher values and as a consequence the correlated parameters follow. Therefore, the accuracy of the model at all scales is critical for not biasing the fitted parameters.

We now analyse the individual mocks for three cases: (1) fitting the complete range [27.5,127.5] $h^{-1}$Mpc using monopole and quadrupole, (2) fitting the complete range [27.5,127.5] $h^{-1}$Mpc using monopole, quadrupole, and hexadecapole, and (3) fitting the complete range [27.5,127.5] $h^{-1}$Mpc for monopole and quadrupole and reducing the range to [47.5,127.5] $h^{-1}$Mpc for the hexadecapole. Fig. 9 show the results of the individual fits in all three cases and for the four parameters of interest [$f_8$, $b_8$, $\alpha$, $\epsilon$], as well as their respective best-fitting distributions histograms. The coloured dashed lines indicate the mean of the best fits, and the dotted line represents the expected value of the parameters. Table 4 presents the results of the individual fits for the parameters of interest.

The monopole- and quadrupole-only fits show a bias in the estimation of the three parameters of $|b_{f_8}| = 0.003$, $|b_8| = 0.002$, and $|b_9| = 0.0004$. The standard deviation of the distributions are $S_f = 0.051$, $S_b = 0.014$, and $S_\epsilon = 0.019$ respectively; the expected values are within the dispersion. Thus the significance of the biases are $0.5\sigma$, $1.1\sigma$, and $0.2\sigma$. These numbers are in agreement with the best performed for the BOSS sample and these numbers are comparable with the results obtained in Alam et al. (2017a).3 The full range hexadecapole fits show a lower bias in the $f$ parameters, with a value of $|b_{f_8}| = 0.0007$, $|b_8| = 0.00008$, and $|b_9| = 0.0002$, respectively. The standard deviation of the distributions decreases for $f$, $\alpha$, and $\epsilon$, with $S_f = 0.037$, $\alpha = 0.013$, and $S_\epsilon = 0.010$. The significance of the biases decreases significantly to $<0.1\sigma$, $0.1\sigma$, and $0.2\sigma$, respectively. Constraining the range of hexadecapole fits, produces biases of $|b_{f_8}| = 5\epsilon - 4$, $|b_8| = 0.001$, and $|b_9| = 5\epsilon - 4$, while also decreasing the standard deviation of the distributions compared with the monopole and quadrupole fits, $S_f = 0.042$, $S_b = 0.013$, and $S_\epsilon = 0.014$, giving a significance of the biases of $0.1\sigma$, $0.9\sigma$, and $0.4\sigma$ respectively. Fig. 10 shows the summary of the analysis for our three cases in the same format as the results reported in Alam et al. (2017a): the points correspond to the mean of the results obtained from fitting our 84 SkyCut with the BOSS mask mocks, the three quantities shown are (from left to right) the mean of $\Delta f = f - f^{exp}$, $\Delta \alpha = \alpha - \alpha^{exp}$, and $\Delta \epsilon = \epsilon - \epsilon^{exp}$, and the error indicated is the standard deviation of our fits. The panels contain the results from: (1) the fits with monopole and quadrupole (left), (2) the fits also including the hexadecapole (middle), and (3) the fits using multipoles up to $\ell = 4$ and using a constrained range on the hexadecapole (right). We also include the result for the growth factor obtained by BOSS and reported in Alam et al. (2017a) (far right value of the left-hand panel).

These results suggest that the most accurate results (smaller parameter biases in all parameters normalized by the dispersion) are obtained using the multipoles up to $\ell = 4$ in the full range.

However, we would like to highlight that we noticed that the best model of the hexadecapole does not accurately match the mean of the mocks (the value of the residuals is close to 50 percent of the value of the model compared to 10 percent and 4 percent for the monopole and quadrupole, respectively). For the individual fits, given the large error bars on the hexadecapole, this mismatch does not bias our individual measurements, but produces small bias in the best fit of the mean in $\epsilon$. Bearing all of this in mind we choose to analyse both cases (with and without hexadecapole), but we will take a conservative approach and report the monopole and

3 The BOSS analysis only reported the result of $\Delta f_8$ for the N-Series Mocks Challenge.
Figure 9. Results from the best fits of all of the individual mocks for the four parameters of interest \([f, b, \alpha, \epsilon]\). Also shown are their respective best fits distributions histograms and the 1\(\sigma\) confidence region. The dotted black lines represent the expected value of each parameter. The coloured lines in each histogram indicate the mean value of that parameter found by our fits. We present three cases: (1) fitting the complete range \([27.5, 127.5]\) \(h^{-1}\) Mpc using monopole and quadrupole (blue dots), (2) fitting the complete range \([27.5, 127.5]\) \(h^{-1}\) Mpc using monopole, quadrupole, and hexadecapole (red x’s), and (3) fitting the complete range \([27.5, 127.5]\) \(h^{-1}\) Mpc for monopole and quadrupole and reducing the range to \([47.5, 127.5]\) \(h^{-1}\) Mpc for the hexadecapole (green crosses).

Table 4. Results from fitting the 84 N-Series sky mocks with our fiducial methodology. The columns denoted by \(\bar{x}\) are the mean, \(S_x\) denotes the standard deviation, and the bias (defined by equation 23) is denoted by \(b_x\), with \(x = f, \alpha, \epsilon\).

| Model         | \(f_{\sigma_8}\) | \(S_f\) | \(b_f\) | \(\bar{\alpha}\) | \(S_\alpha\) | \(b_\alpha\) | \(\bar{\epsilon}\) | \(S_\epsilon\) | \(b_\epsilon\) | \(N_{\text{mocks}}\) |

quadrupole only analysis as our final result of this work. Based on the results from N-Series we adopt \( \sigma_{\epsilon}^{SYS} = 0.004 \), \( \alpha^{SYS} = 0.001 \), and \( \sigma_\alpha^{SYS} = 5\epsilon - 4 \) as an estimate of the potential bias of \( f, \alpha \), and \( \epsilon \).

### 6.2 Testing systematics with eBOSS-mocks

We will dedicate this section to test the variance of the methodology developed in Section 4. This analysis will be done using two sets of approximative mocks, the QPM and EZ described in Section 3, both built with the same properties of our eBOSS sample. The mocks were calibrated to match the data, however, these approximative mocks lack the accuracy to study the biases of our methodology. As shown in Fig. 11, the QPM and EZ mock have a small bias in the monopole at small scales. Additionally, both seem to systematically underestimate the hexadecapole. Bearing this in mind, our estimates of the bias will only come from the results of the N-Series Cut-sky mocks obtained in the last section, we proceed to quantify the dispersion of the fitting methodology. Our specific goal is to estimate the dispersion expected around the parameters of interest of our model. This will be done by applying the fitting methodology from Section 5.3 to 100 of our individual QPM an EZ mocks, which will give us 100 estimates of the best-fitting values.

We test two cases: (1) Considering only the multipoles up to \( \ell = 2 \) (skipping the hexadecapole), and therefore following the methodology used in previous analysis performed with the LRG sample, which we will refer to as \( '\xi_0 + \xi_2' \). We also consider the effect of extending the multipoles up to \( \ell = 4 \) and using the full range for all multipoles, which we will refer to as \( '\xi_0 + \xi_2 + \xi_4' \).

We used the cosmology use for the QPM mocks generation in order to compute their comoving coordinates, and the fiducial cosmology for computing those of the EZ mocks. Table 5 summarizes the results from our fits. The first block corresponds to the monopole + quadrupole fits using the QPM/EZ mocks; the second block describes the analysis adding the hexadecapole to our fits. The dispersions obtained from our two sets of mocks when only using the monopole and the quadrupole in the fits (first block of Table 5) are fairly consistent for all of the parameters of interest: \( \sigma_{f}^{QPM} = 0.113 \), \( \sigma_{\epsilon}^{QPM} = 0.122 \), \( \sigma_{\alpha}^{QPM} = 0.039 \), \( \sigma_{\epsilon}^{EZ} = 0.043 \), and \( \sigma_{\alpha}^{EZ} = 0.044 \). The dispersion is also consistent with previous results found on the anisotropic LRG DR14 BAO analysis from Bautista et al. (2018) where: \( \sigma^{BOSS} = 0.048 \) and \( \sigma^{BAO} = 0.055 \).

In order to compare with the previous results from BOSS reported in Alam et al. (2017b), we need to rescale the variance using the differences in volume between the two samples; the effective volume of our sample is 0.9 Gpc\(^3\) while BOSS–CMASS accounts for 4.1 Gpc\(^3\) in the [0.5, 0.75] redshift slice. The CMASS sample reported the following standard deviations for the [0.5, 0.75] redshift slice: \( \sigma_{f}^{CMASS} = 0.058 \), \( \sigma_{\epsilon}^{CMASS} = 0.016 \), and \( \sigma_{\alpha}^{CMASS} = 0.022 \) (table 6 of Alam et al. 2017b), we can scale them roughly to the eBOSS volume using \( \sigma_{f}^{eBOSS} = (\Delta)^2/4.1 \) Gpc\(^3\))/0.9 Gpc\(^3\), yielding the following scaled dispersions: \( \sigma_{f}^{eBOSS} = 0.124 \), \( \sigma_{\epsilon}^{eBOSS} = 0.034 \), and \( \sigma_{\alpha}^{eBOSS} = 0.047 \). These values are in agreement with the dispersion obtained with our QPM/EZ mocks.

Now, let us examine the fits that include the hexadecapole. The dispersion obtained from the two sets of mocks is also consistent for the parameters \( f, \epsilon \): \( \sigma_{f}^{QPM} = 0.090 \) and \( \sigma_{\epsilon}^{QPM} = 0.089 \), and \( \sigma_{\alpha}^{QPM} = 0.050 \) and \( \sigma_{\alpha}^{QPM} = 0.028 \). Also we observe the dispersion in all parameters decreases when considering the hexadecapole as expected.

Fig. 12 shows the distribution of the differences between the parameters of interest and their expected values on a mock-by-mock basis, i.e. \( \Delta f = f - f_{\text{exp}} \), \( \Delta \alpha = \alpha - \alpha_{\text{exp}} \), and \( \Delta \epsilon = \epsilon - \epsilon_{\text{exp}} \). Reviewing the monopole + quadrupole fits (in blue dots) reveals that both sets of mocks show a well-behaved distribution that is centred close to zero and is symmetric. From the hexadecapole fits (red x’s), we also observe symmetric distributions centred around zero, however, especially the 1D distributions for the \( f_{\text{exp}} \) and \( \epsilon_{\text{exp}} \) parameters are slightly shifted.

These shifts in the distributions when considering the hexadecapole are related to the QPM/EZ mocks poor precision and to the fact that the model and the mean multipoles present mismatches, the following paragraphs will briefly show these mismatches. As
we will see, the biggest mismatch between mock and model occurs in the hexadecapole for the QPM mocks and in the quadrupole for the EZ mocks.

Fig. 13 shows a comparison between the mean of the mocks and the model templates built with the true cosmology of the mocks\(^\ddagger\) denoted by ‘Model GS \(f(z = 0.72)\)’. The left-hand panel shows the comparison between the mean of the QPM mocks and its model template and the equivalent comparison for the EZ mocks is in the right-hand panel. The growth factor used for building the model in the right-hand panel is at the effective redshift of the mocks. Indeed, the 3-point correlation function of EZmocks (fig. 8, Chuang et al. (2015)) is more consistent with N-body simulations, compared to QPM (Fig. 10, White et al. 2014, QPM paper). Since the high order statistics of EZmocks are better, the high order multipoles are also more reliable. Thus we can expect to get better fits when using the hexadecapole information.

From this analysis we can draw the following conclusions. First, the GSRSD model cannot match the multipoles of the QPM mocks, as they show a mismatch in the mean of the mocks and the model for the quadrupole, giving rise to a higher value than the input value of the simulations. Secondly, the model of the hexadecapole is systematically larger than the mean of the mocks, and in particular any conclusion about the bias of the hexadecapole cannot be extracted from the fits of the QPM mocks.

The right-hand panel of Fig. 13 shows an equivalent comparison between mean and model template using the EZ mocks. As for the QPM mocks we also see a mismatch, but this time between the small scales of the quadrupole: the template with the cosmology and redshift of the EZ mocks (red dotted line) does not match with the mean quadrupole of the mocks (black solid line).

It is interesting to notice that the mean hexadecapole matches the template. EZ mocks describes better the hexadecapole than QPM because the effective bias model encoded in EZ mocks accounts for both 2- and 3-point statistics (Chuang et al. (2015), EZmock paper).

Indeed, the 3-point correlation function of EZmocks (fig. 8, Chuang et al. (2015)) is more consistent with N-body simulations, compared to QPM (Fig. 10, White et al. 2014, QPM paper). Since the high order statistics of EZmocks are better, the high order multipoles are also more reliable. Thus we can expect to get better fits when using the hexadecapole information.

We also notice that the mismatch in the quadrupole behaves different for different scales, the scales lower than \(50\ h^{-1}\) Mpc are overestimated and the scales larger than \(50\ h^{-1}\) Mpc are underestimated. Thus, the EZ mocks seem to not be reproducible by the model. Apparently, the template with the mocks cosmology fits the mean better, but the template is not capable of fitting all of the scales of the quadrupole and the hexadecapole simultaneously.

\(\ddagger\)the cosmology used for building the mocks.
Figure 12. Scatter triangle plots comparing fits for full shape fits using $\xi_0 + \xi_2$ (blue dots) and $\xi_0 + \xi_2 + \xi_4$ (red x’s) for QPM (up) and EZ (down) mocks. We show the difference of the best-fitting values with respect to the expected values for each of the parameters of interest. The means are indicated as solid lines for the two cases explored. The dotted lines indicate the expected values, which are zero for all cases.
We can summarize the results of this section as follow: (1) the dispersion obtained from both sets is consistent with each other and with previous results from BOSS (Alam et al. 2017b) and from the DR14 BAO group (Bautista et al. 2018). (2) both sets of eBOSS mocks lack the accuracy to study the biases of our methodology: the QPM mocks seem to slightly overpredict the quadrupole expected by the GSRSD model and are not a good match to the hexadecapole. The EZ mocks have a better match to the hexadecapole, but cannot match the quadrupole at small scales (lower than 50 $h^{-1}$ Mpc).

6.3 Comparison of AP parameters results with BAO-only fits

In this section, we compare our results to those obtained in Bautista et al. (2018), which is a previous analysis using this same sample. The left-hand panel of Fig. 14 shows the difference between our QPM FS fits to the combined sample and the expected value compared to those from the anisotropic BAO parameters, the later taken from Bautista et al. (2017). The dispersion for the anisotropic warping, $\epsilon$, from BAO fits is slightly larger compared to the FS best fits. In an RSD analysis other parameters that affect the quadrupole are included (most significantly the growth factor $f$), so it is not surprising that FS analysis breaks some degeneracies in $\epsilon$ and reduces its dispersion. There is also a small shift in the isotropic dilation parameter, $\alpha$, when comparing the FS analysis best fits to those coming from BAO. The left-hand panel of Fig. 14 shows the scatter plot for $\alpha$, with a Pearson correlation factor of $r = 0.5$. There are several differences in the fitting methodology between these two fits. Obviously the modelling of the signal is different in BAO and in our RSD + AP model, but in addition the fitting range used in BAO is wider in its $r$-range that is extended to 180 Mpc $h^{-1}$ while our FS analysis is constrained to $r$-values lower than 130 Mpc $h^{-1}$. Also, the binning used in BAO is 5 Mpc in width, while this work is using bins with a width of 8 Mpc.

6.4 Testing the impact of spectroscopic incompleteness

To test the effect of redshift incompleteness in our clustering, we consider three cases: the first is our mock catalogues with no redshift failures. Then, we study the effect of the two mitigation techniques described in Section 2.3.2. The redshift failures are added to the mocks by associating a position in the plate to each galaxy, then the catalogue of binned probabilities is used to mimic the effect of the redshift failures observed in our data. The second case explored is the up-weighting methodology, and finally, for the third case, the forward-modelling technique.

Fig. 15 displays the impact of different mitigation methods on the average of all 1000 mock catalogue correlation functions. The three lines represent the case without redshift failure corrections and the up-weighting and forward modelling corrections. While the monopole is equally well recovered in all three cases, the quadrupole shows a clear shift (i.e. bias) at all scales when using the up-weighting method. The forward-modelling corrections recover the expected values for scales smaller than $r = 140$ Mpc $h^{-1}$, but show slight discrepancies at larger scales.

Table 6 lists the results of the best-fitting parameters found by fitting all 100 QPM mocks using both correction schemes. We compared the results of the mocks where redshift failures are applied and corrected by one of the two mitigation techniques with the case where no redshift failures are considered. We report the difference of the mean of the best fits as an indicator of the systematic bias related to the spectroscopic completeness denoted by $\Delta f$, $\Delta \alpha$, and $\Delta \epsilon$; we also report the dispersion $S_x$, where $x = f, \alpha, \epsilon$. We observe that the up-weighting technique differs from the case without redshift failures by $\Delta f = 0.016 (\Delta f/\sqrt{N_{\text{sim}}}) \sim 0.7 \sigma$, $|\Delta \alpha| = 0.001 (0.1 \sigma)$, $|\Delta \epsilon| = 0.003 (0.7 \sigma)$. When using the forward modelling, the systematic error reduces to $|\Delta f| = 0.004 (0.1 \sigma)$, $|\Delta \alpha| = <0.001 (<0.1 \sigma)$, and $|\Delta \epsilon| = 0.005 (0.8 \sigma)$. There is an increase...
Growth rate measurement from LRG clustering

Figure 14. Left-hand panel: A comparison of the BAO fits and full shape using $\xi_0 + \xi_2$ for the mocks. Right-hand panel: comparison of best fits in isotropic dilation parameter for FS and BAO for the mocks. The dispersion for the anisotropic warping, $\epsilon$, from BAO fits is slightly larger compared to the FS best fits. FS analysis breaks some degeneracies in $\epsilon$ and reduces its dispersion.

Figure 15. Impact of the redshift completeness on the multipoles and the effect of the mitigation techniques for correcting potential biases. The monopole (top), the quadrupole (bottom), and hexadecapole (middle) are presented in three cases: without redshift failures, correcting by the up-weighting technique, and correcting using the Forward modelling technique. While the monopole is well recovered by the two correction techniques, the quadrupole/hexadecapole shows a clear shift (i.e. bias) at all scales when corrected with the up-weighting method. The forward-modelling recovers the expected values for scales smaller than $r = 140 \, h^{-1} \, \text{Mpc}$.

7 RESULTS ON THE LRG DR14 SAMPLE

We performed the analysis on the eBOSS–CMASS sample combining the NGC and SGC (if not otherwise stated). The covariance matrices used in our fits were rescaled by a factor of 0.9753 in order to account for the slight mismatch between the footprint area of the data and of the mocks.

Before running a full Monte Carlo Markov Chains (MCMC) analysis, we will compute the best-fitting parameters using the minimization methodology of the last chapter, which will help us understand how susceptible our models are to changes in the distance range of our analysis.

While these results were not expected to provide any information on the confidence contours of our parameters (as an MCMC would), they give an idea of the maximum likelihood values. The main reason for performing these tests is that our MCMC analysis in its current implementation is prohibitively time-consuming; we simply cannot afford to run all the tests on our data using a full MCMC approach (as we will see in appendix A, our models can be degenerated when using broad biases, how large the biases can be depends on the range of the bins and on the error sizes. These degeneracies make the convergence significantly slower). Further development needs to be done in order to reduce the time of convergence of our final analysis. These maximum likelihood tests can also be used as a check of the robustness of our MCMC results.

Our first test compares the robustness of the fit against variations in the maximum fitting range (the maximum distance in $h^{-1} \, \text{Mpc}$ where the correlation function is measured). This test is particularly important in our analysis. Fig. 5 shows that the quadrupole estimates made with the data show large correlations at scales larger than $100 \, h^{-1} \, \text{Mpc}$, which are outside the variance observed in the mocks. This anomalous correlation at large scales affects the capability of our model to fit the data multipoles. We suspect this behaviour could be related to an unknown systematic or a statistical fluctuation. Given that we could not identify any systematic that affects the quadrupole, and that we cannot exclude a large fluctuation, we also analysed the behaviour of the fits when those large scales are eliminated in all multipoles with $\ell \geq 2$. Our main result, however, is quoted with the complete range. If this behaviour is repeated in the DR16 analysis, that will indicate a systematic error that needs to be analysed properly to provide non-biased results. If the origin of
this correlation is a statistical fluctuation, this feature will probably be diluted with an increase in volume.

Thus, before exploring the likelihood surface, we performed some maximum likelihood fits using a variety of ranges. The fiducial case uses the complete range between [28,124] \( h^{-1} \) Mpc for the multipoles up to \( \ell = 0, 2, 4 \). We also tested some variants of this range to investigate the impact of cutting the large scale of each multipole on the best fits.

Table 7 lists the results of the best fits for the fiducial cases and several variants and Fig. 16 shows how the best fit models compare to the data. From Table 7, we conclude that reducing the range of the fit from 128 to 92 \( h^{-1} \) Mpc improves the goodness of the fit for both the monopole + quadrupole fit and the monopole + quadrupole + hexadecapole fit. The \( \chi^2/\text{d.o.f.} \), a measurement of the goodness of a fit, reduces from 2.1 to 1.35 for the \( \ell_{\text{max}} = 2 \) case (However, there is no reduction when we reduce the range for both monopole and quadrupole where \( \chi^2/\text{d.o.f.} \) stays at 2.09), and from 1.81 to 1.16 if we eliminate large scales for all \( \ell = 0, 2, 4 \) (It stays the same if we only limit hexadecapole, 1.14 if we restrict the range of the large scales for both \( \ell = 2, 4 \) but not for the monopole).

By using the complete range we increase the discrepancy between the fits using different order multipoles (i.e. \( \ell_{\text{max}} = 2 \) versus \( \ell_{\text{max}} = 4 \)). The difference in the best-fitting parameters for the growth factor \( f \) is 0.211 for the complete ranges (row one minus two), and it becomes 0.139 when reducing the quadrupole and hexadecapole ranges to [28,92] \( h^{-1} \) Mpc (row three minus six). Similar trends occur with \( \epsilon \), where the differences in the best-fitting values range from 0.064 to 0.042. These trends indicate that the large correlation observed in the quadrupole is not properly modelled by our CLPT-GSRSR template. When we exclude the large scales of the monopole, there is a significant shift in both \( f \) and \( \epsilon \), with \( f \) shifting from 0.905 to 0.589 and \( \epsilon \) from –0.026 to 0.088. These shifts are expected when eliminating the large scales on the monopole. Finally, excluding the large scales on the hexadecapole affects the \( f \) fits, and mildly affects the \( \epsilon \) fits, as the quadrupole and hexadecapole capacity to break the degeneracy between \( f \) and \( \epsilon \) is derived from the BAO scales. The goodness of the fit, \( \chi^2/\text{d.o.f.} \), improves when removing the large scales, due to the incapability of modelling the anomalous correlation; this approach loses all the information encoded in the BAO in the quadrupole and hexadecapole. Consequently, the results for the AP parameters are degraded and potentially biased. We will perform the MCMC exploration for the same four cases for completeness, but we will quote the full range as our final result.

As stated, we used an MCMC methodology for exploring the likelihood surface, which was done using the Monte Python public code (Audren et al. 2013). We use flat priors for our parameters; the range of these priors is presented in Table 8. We run two different chains in the combined data set (NGC + SGC). The first is with the monopole and quadrupole only (\( \xi_0 + \xi_2 \)) and using the fiducial distance range. The second chain also runs with the monopole and quadrupole (\( \xi_0 + \xi_2 \)), but restricting the range in the quadrupole to [28,92] \( h^{-1} \) Mpc (the monopole stays in the same range of [28,124] \( h^{-1} \) Mpc). Table 9 displays the results from the MCMC analysis. Our final measurement was performed on the combined sample, which includes the NGC and the SGC, and was done using the fiducial methodology (i.e. 8 \( h^{-1} \) Mpc bins on the fiducial range).

The first block reports the final result of this work, the monopole and quadrupole-only fits. The second block is for the \( \xi_0 + \xi_3 \) fits when excluding the large scales of the quadrupole. The third block lists the results for the Galactic hemispheres separately, this is shown for identification of any residual systematics in the data; we will discuss these results at the end of this subsection. The fourth block is quoted as a reference and it shows the fits of the BAO-only analysis done with this same sample in Bautista et al. (2018). MCMC chains using the hexadecapole are included in the final block for completeness and discussed in the Appendix B as a robustness test, but it is not part of our main results.

Fig. 17 shows the likelihood surfaces for the two runs over the \( \xi_0 + \xi_2 \), one chain is in the fiducial range and the other is eliminating the large scales for the quadrupole, i.e. [28,92] \( h^{-1} \) Mpc. The latter is added for completeness, but as stated before, our final result will be quoted using the full range. The figure contains the 1–2\( \sigma \) confidence contours for the growth factor \( f, \) the linear bias \( b_s \), the dilatation parameter \( \alpha \), and the warping parameter \( \epsilon \), together with their marginalized 1D distributions. The 1–\( \sigma \) regions are fully contained inside our priors for both cases. However, the 2–\( \sigma \) regions are cut by our prior to large values of \( \epsilon \) and small values of \( \alpha \), our reasons for not using larger priors on the Alcock-Paczynski parameters will be discussed in the Appendix A.

The results of \( f, \alpha, \) and \( \epsilon \) are consistent within 1\( \sigma \), for both ranges. However, given the anticorrelation between the \( \epsilon \) and \( f \) parameters and the fact that the quadrupole is dominated by \( \epsilon \) at the larger scales, when including the larger bins of the quadrupole the \( \epsilon \) is driven from its expected value and as a consequence \( f \) shifts as well. When the last three bins of the quadrupole are avoided we achieve a significant improvement in the goodness of the fit towards \( \sim 1 \); the price paid for this approach is to eliminate the BAO information. This increases the degeneration of the parameters and biases the results, thus we lose information that constrains \( \epsilon \), which in turn causes the contour areas to become larger, providing more freedom to the fitter to move \( f \) to lower values (Fig. 17).

Finally when comparing the results for the \( \xi_0 + \xi_2 \) with the fit using \( \xi_0 + \xi_2 + \xi_4 \), we find agreement within \( 1 – \sigma \) for \( f, \alpha \) and \( \epsilon \), but the \( \epsilon \) values have a 1.3 – \( \sigma \) difference. We should notice that tighter priors were used for hexadecapole because a bi-modality appears using the priors defined in Table A, more discussion about the results and the prior selection for the hexadecapole is provided in the Appendix B.

Fig. 18 displays the best-fitting anisotropic models compared to the data for our fiducial choice of analysis. As expected, the monopole and quadrupole are visually good fits for the data, except for the large scales of the quadrupole where the correlation becomes strongly positive (scales larger than 90 \( h^{-1} \) Mpc).

To finalize this section, we analyse separately the NGC and the SGC. Fig. 19 displays the 1\( \sigma \) and 2\( \sigma \) confidence contours obtained from running an MCMC analysis separately on both hemispheres. They are computed using our standard priors quoted in Table 8. The contours in both galactic caps are poorly defined and the 1\( \sigma \) interval in \( \epsilon \) and \( \alpha \) are sharply cut by our imposed priors.

As discussed in appendix A our methodology has difficulty on fixing the AP parameters to a unique value given the size of our errors compared to the strength of the BAO signal, this leads to unphysical values of \( \epsilon \) and \( \alpha \) (and therefore \( f \) due to their correlation with \( \epsilon \)) being accepted by the MCMC chain and affects all of the constraints of our parameters.

Given that the errors are larger for the North and the South separately that in the combined sample, the degeneration is stronger. This leads to several regions being accepted to within 1–\( \sigma \) that would otherwise be rejected due to their inability to reproduce the BAO peak. More data will tend to reduce this behaviour and that is in fact what we see in the combined sample, where the errors are smaller.

Fig. 20 presents the data multipoles for the NGC (blue points) and SGC (red x’s); the error bars correspond to their 1–\( \sigma \) variance from
the quadrupole range to \([28,92]\) \(h = \ell\) multipoles up to Figure 16. The maximum likelihood model for four cases: (1) using \(\ell = -4\) but restricting the range of the quadrupole and hexadecapole to \([28,92]\) \(h\) for the fiducial range, (2) using multipoles up to \(1\) Mpc, and (4) using multipoles up to \(\ell = 4\) but restricting the range of the quadrupole and hexadecapole to \([28,92]\) \(h\) Mpc.

Table 6. Testing for Redshift Failures. Fitting results from 100 QPM mocks using two different techniques for mitigating the redshift failures. We compared the results of the mocks where redshift failures are applied and corrected by one of the two mitigation techniques to the case where no redshift failures are considered. We report the difference of the mean of the best fits as an indicator of the bias related to the spectroscopic completeness denoted by \(\Delta f, \Delta \alpha, \Delta \epsilon\) and we also report the dispersion by \(\Delta S_x\), where \(x = f, \alpha, \epsilon\).

| Mitigation methodology | \(\Delta f\) | \(S_f\) | \(\Delta \alpha\) | \(S_{\alpha}\) | \(\Delta \epsilon\) | \(S_{\epsilon}\) | \(\Delta F\) | \(\Delta F'\) | \(\Delta S_{FOG}\) |

the sample covariance matrix computed using the QPM mocks. The blue solid line represents the fits made by our MCMC analysis in the NGC, the red dashed line is the analogue for the SGC. These fits are done using the mean values obtained by our MCMC chains, which we use as our estimates of the best fits. The NGC and SGC have a significant difference in the clustering amplitude at small scales, and the peak is shifted in one hemisphere compared with the other (it is not well defined in either of the hemispheres). Both models reasonably reproduce the multipoles; this is especially true in the smaller scales which are the ones with more weight in the fit (due to their smaller variance). There is a difference in the multipole amplitude between both galactic caps, as a consequence the contours in Fig. 19 are displaced among each other, the results of the combined sample surrounds the regions where both contours intercept (see Table 9).

Figure 16. The maximum likelihood model for four cases: (1) using multipoles up to \(\ell = 2\) in the fiducial range, (2) using multipoles up to \(\ell = 4\) for the fiducial range, (3) using multipoles up to \(\ell = 2\) but restricting the quadrupole range to \([28,92]\) \(h^{-1}\) Mpc, and (4) using multipoles up to \(\ell = 4\) but restricting the range of the quadrupole and hexadecapole to \([28,92]\) \(h^{-1}\) Mpc.

8 COSMOLOGICAL IMPLICATIONS

Table 10 presents our final constraints on the growth factor \(f_{\sigma,8}\), the angular diameter distance \(D_A(z)\), and the Hubble parameter.
Table 9. Results for the DR14 LRG sample. The first block is for our fiducial methodology, using the fiducial range for the $\xi_0 + \xi_2$ fit. The second block is for the $\xi_0 + \xi_2$ fits when excluding the large scales of the quadrupole. The third block shows the fits separating the hemispheres NGC and SGC and using $\xi_0 + \xi_2$ in the fiducial range. The fiducial value for the $\sigma_8(z_{eff} = 0.72)$ = 0.55. The Eulerian bias is defined as $b = 1 + F$.  

![Figure 17](https://example.com/figure17.png)  

Figure 17. The shaded regions show the 1–2$\sigma$ confidence surfaces found by our MCMC chains for the RSD-AP parameters for the $\xi_0 + \xi_2$ space in the fiducial range (blue solid) and when excluding the large scales in quadrupole (red dashed). The confidence contours for the growth factor $f\sigma_8$, the linear bias $b\sigma_8$, the dilatation parameter $\alpha$, and the warping parameter $\epsilon$ are indicated, along with their 1D distributions. The dashed lines of each histogram are the mean values found by the MCMC chain.

$H(z)$ including the statistical and the systematic error.$^6$ Our fiducial cosmology was used to convert the best-fitting dilatation parameters $\alpha_0$ and $\alpha_1$, into distance measurements. The table includes the same variants of the methodology quoted in Table 9 for the combined sample, and the values are in agreement with each other within 1$\sigma$.

![Figure 18](https://example.com/figure18.png)  

Figure 18. This plot shows how our data (black dots) compares to our model (red solid line). The model is built using the values from the first line of Table 9, that were computed using multipoles up to $\ell = 2$ and our combined sample (NGC + SGC) in the fiducial range. The model is visually a good fit for the data, except for the large scales of the hexadecapole.

Our final constraint, the logarithmic growth of structure multiplied by the amplitude of dark matter density fluctuations, is $f(z_{eff})\sigma_8(z_{eff}) = 0.454 \pm 0.134$. Using the AP dilation scales allowing us to constrain the angular diameter distance and the Hubble distance we arrive to: $D_A(z_{eff}) = 1466.5 \pm 133.2 (r_s/r_{s\,\text{fid}})$ and $H(z_{eff}) = 105.8 \pm 15.7 (r_s/z_{eff})$ km s$^{-1}$ Mpc$^{-1}$ where $r_s$ is the sound horizon at the end of the baryon drag epoch and $r_{s\,\text{fid}}$ is its value in the fiducial cosmology at an effective redshift $z_{eff} = 0.72$. These measurements correspond to relative errors of 29.4 per cent.

$^6$The systematic error is based on the results from N-Series.
Growth rate measurement from LRG clustering

Figure 19. Equivalent to Fig. 17 but presenting the MCMC chains for the RSD-AP parameters in the NGC (blue solid) and in the SGC (red dashed); both of them are in the fiducial range.

Figure 20. The blue dots and red x’s represent the NGC and the SGC measured data points for the Monopole (top) and the Quadrupole (bottom). The errors bars are the standard deviation computed using the QPM mocks. The solid lines indicate the best model found by the MCMC for the NGC/SGC.

9.1 per cent, and 14.9 per cent, respectively, considering the systematic error.

Bautista et al. (2018)’s analysis with the DR14 LRG sample reported a low statistical power of the current sample, and generated anisotropic BAO results yielded slightly worse results than isotropic fits. Further data releases from eBOSS should increase the statistical significance of our measurements.

Fig. 21 presents our measurements compared with previous results from SDSS-III-BOSS DR12 from both galaxies (Alam et al. 2017a) and Lyman-alpha quasars (du Mas des Bourboux et al. 2017; Bautista et al. 2018), the eBOSS quasar measurements from Gil-Marín et al. (2018), Zarrouk et al. (2018), Hou et al. (2018),7 and the Main Galaxy Sample (MGS) from SDSS-II-DR7 (Ross, Percival & Manera 2015). Our measurements are consistent with previous analyses and the ΛCDM model.

Our measurements with the CMASS–eBOSS sample are correlated with the CMASS measurements. The correlation coefficient between the two measurements was roughly estimated to be 0.16 (Bautista et al. 2018); a proper measurement of this correlation will be achieved for the DR16 analysis.

9 CONCLUSIONS

The RSD effect generates an artificial anisotropy on the clustering of galaxies which can be used to constrain the growth factor, \( f(z) \sigma_8 \), and the radial and angular distances to the sample (i.e. the \( H(z) \) and \( D_A(z) \) parameters). We used the LRG sample from the first two years of the eBOSS, denoted as DR14, to measure these parameters at the mean redshift of the survey (\( z = 0.72 \)). We presented the first full-shape analysis of this sample (i.e. modelling RSD simultaneously with an AP parametrization), and that should

\[
P_{\text{obs}}(k, \mu) = \frac{1}{\alpha r^2} \left[ b \sigma(z) + \frac{f \sigma_8(z) \mu^2}{A^2 + (1 - A^2) \mu^2} \right]^2 \]

where \( A = \alpha_r / \sigma_8 \) denotes the relative distortion in the radial and transverse directions due to the AP effect. \( P_{mm} \) and \( P_{gg} \) are, respectively, the matter and galaxy power spectrum; \( n \) is the number density of the galaxies. The uncertainties on the BAO and RSD parameters are estimated by computing the Fisher matrix from the observed galaxy power spectrum, \( F_{ij} \), following Tegmark (1997) with the parameter set \( \mathbf{p} = \{ \ln(\alpha_r), \ln(\alpha_\perp), \ln(b \sigma_8), \ln(f \sigma_8) \} \). In order to account for the error induced by redshift uncertainties, we multiply the integrand of \( F_{ij} \) by a damping factor of \( \exp[-(k \mu \sigma_8)^2] \), where \( \sigma_8 = \partial \sigma / \partial z \) and \( r \) is the comoving distance.

The second block of Table 10 lists the forecast when including the AP test. The measurements of \( H(z) \), \( D_A \), and \( f \sigma_8 \) are, respectively, 3.9, 3.1, and 2.6 times larger than the predictions. While this result might be caused by the non-uniform footprint of the sample at its current state, the BAO measurements also reported errors larger than the predictions.

CONCLUSIONS

The RSD effect generates an artificial anisotropy on the clustering of galaxies which can be used to constrain the growth factor, \( f(z) \sigma_8 \), and the radial and angular distances to the sample (i.e. the \( H(z) \) and \( D_A(z) \) parameters). We used the LRG sample from the first two years of the eBOSS, denoted as DR14, to measure these parameters at the mean redshift of the survey (\( z = 0.72 \)). We presented the first full-shape analysis of this sample (i.e. modelling RSD simultaneously with an AP parametrization), and that should

7Fig. 21 quotes the (Gil-Marín et al. 2018) result; however, the three measurements from the different analyses were shown to be fully consistent.
significant biases in the distributions, when fitting the mean we
noticed that the model hexadecapole does not accurately match the
mean of the mocks, this generates small biases in the fits of the
mean $\epsilon$ parameter. The reason why this mismatch does not bias our
measurements in the individual realizations is because of the larger
errors bars we have on the hexadecapole. This behaviour is related
to the fact that the fits are driven by $\epsilon$ when we include the lower
bins of the hexadecapole. The error bars for those lower scales are
smaller, and therefore their constraining power is larger. This makes
the accuracy of the model at small scales critical.

In order to characterize the statistical properties of the sample,
especially its variance, we ran our fitting methodology on two
different sets of low-precision mocks with eBOSS properties: the
QPM and EZ mocks. All of the mocks in both sets are fitted twice,
the first considering only the multipoles up to $\ell = 2$, and the second
with multipoles up to $\ell = 4$. The dispersion obtained from the
two sets of low-precision mocks was fairly consistent in all cases
and for all of the parameters of interest. However, the biases and
distributions were not consistent with those obtained using high-
precision mocks. The discrepancy arises because the GSRSD model
cannot match the multipoles of QPM/EZ mocks, thus no conclusion
about the bias could be extracted from these fits. They were only
used as a reference for the variance of the best fits for eBOSS-like
mocks.

The tests performed with mocks (high and low precision),
demonstrated that the constraining power of the lower bins of
the hexadecapole is large due to the smaller error bars of those
points. We concluded that including the hexadecapole is desirable;
however, it becomes critical to have accurate models, particularly
of the small scales of the quadrupole and the hexadecapole. In
this work, we adopted the conservative approach of reporting the
$\xi_0 + \xi_2$ as our final result and used the hexadecapole results only
as a consistency test.

We considered that even if the results with high-precision mocks
validated fitting the hexadecapole with our model, the biases
observed when fitting the mean and the mismatch in the model
hexadecapole for the mean needs further exploration. Additionally,
we did not have high-precision mocks with the properties of the
eBOSS sample available (higher redshift and lower mean density)
and we could not properly study the statistical properties of the
fitting methodology with low-precision mocks.

Our final measurement was performed on the 'combined' sample,
using the fiducial methodology considering only the monopole
and quadrupole. We constrained the logarithmic growth of structure
$\xi_0 = 0.454 \pm 0.134$, $\alpha_{\perp} = 0.954 \pm 0.149$, and $\alpha_{\parallel} = 0.955 \pm 0.083$.

The eBOSS DR14 LRG sample presents a large correlation in the
large-scale quadrupole that lies outside the 1σ variation observed in
the mocks. This feature could be related to an unknown systematic
effect or just a large statistical fluctuation. Given that we could
not find any systematic that affects the quadrupole, and that a large

Figure 21. Measurements from DR14 eBOSS-CMASS sample using
multipoles up to $\ell = 2$ (red start) fitting in the range [24,128] $h^{-1}$ Mpc.

Measurements with LRG sample DR14

Forecast

BAO-only

Downloaded from https://academic.oup.com/mnras/article/492/3/4189/5691332 by California Institute of Technology user on 26 March 2020
fluctuation cannot be excluded, we analysed the behaviour of the fits when we eliminated those large scales in multipoles with $\ell > 2$ as a robustness test for our main result. Avoiding the latest three bins of the quadrupole achieves a significant improvement in the goodness of the fit to $\sim 1$; however the price paid is to eliminate the BAO information, which increases the degeneration of the parameters and biases the results, thus we lose information that constrains $\epsilon$, and the contour regions become larger, giving more freedom to the fitter to move $f$ to lower values.

We quote as our final cosmological constraint the logarithmic growth of structure multiplied by the amplitude of dark matter density fluctuations, $f(z_{\text{eff}})\sigma_8(z_{\text{eff}}) = 0.454 \pm 0.134$, and the AP dilation scales which allow constraints to be placed on the angular diameter distance $D_\Lambda(z_{\text{eff}}) = 1466.5 \pm 133.2(r_s/r_s^{\text{fid}})$ and the Hubble distance $H(z_{\text{eff}}) = 105.8 \pm 15.7(r_s^{\text{fid}}/r_s)\text{km}\cdot\text{s}^{-1}\cdot\text{Mpc}^{-1}$, where $r_s$ is the sound horizon at the end of the baryon drag epoch and $r_s^{\text{fid}}$ is its value in the fiducial cosmology at an effective redshift $z_{\text{eff}} = 0.72$. These measurements correspond to relative errors of 29.4 per cent, 9.1 per cent, and 14.9 per cent, respectively, considering the systematic error.

Our results are consistent with previous measurements and with a $\Lambda$CDM model using Planck 2018 cosmology. Comparing our result with the forecasted ones, the measurements of $H(z)$, $D_\Lambda$, and $f(z)$ are respectively, about 3.9, 3.1, and 2.6 larger than the predictions. This result might be caused by the non-uniform footprint in the current state of the survey, although the BAO DR14 LRG measurements also reported errors larger than the predictions (Bautista et al. 2018). We expect a reduction on the statistical error of a factor two by the end of the experiment for DR16 final analysis.

APPENDIX A: SELECTING PRIORS

As discussed in chapter 7, Fig. 17 shows that the 1-σ regions are fully contained inside our priors. However, the 2-σ regions are clearly cut by our prior to large values of $\epsilon$. In this section we will discuss our reasons for not using larger $\epsilon$ priors in our analysis, as we will see prior selection was challenging giving the size of our errors.

Fig. 18 shows a comparison between our final model and the multipoles of the data set, it is clear that the detection of the BAO signal is week: the error-bars of the monopole have a similar size to the power of the BAO peak. This is problematic as the BAO peak locks the AP parameters around a specific value. Given the limited capability of our methodology to fix the cosmology model is vulnerable to being degenerated. As a consequence, we have to be very careful when choosing our priors as a large prior in the AP parameters will result in degenerated regions contributing significantly to our statistics.

This is shown in Fig. A1 where we have run a second MCMC chain of our fiducial methodology but extending the priors of $\epsilon$ to $[-0.3, 0.3]$. These chains were done with a fixed value of $F_2 = 0$ to save computational time as the goal is not to obtain precise statistics but to show the effect of larger $\epsilon$ priors ($F_2$ contributions to our model corresponds to second-order corrections on small scales, primarily broadening the parameter contours). The priors for the other parameters (i.e. neither $\epsilon$ nor $F_2$) stay at the value quoted in Table 8.

In Fig. A1, the solid-line blue contours show our default results, while the dashed-line red ones show those with the enlarged priors on $\epsilon$. A second locus is present for large values of $\epsilon$ and small values of $f_{\sigma_8}$. This second locus is centred somewhere around $f \approx 0.3$ assuming a nominal $\sigma_8$ value consistent with Planck ($\sigma_8(CD)=0.55$), which would result in the AP parameters switching the cosmology to $\Omega_{s8}(z = 0) \approx 0.03$ for $\sigma_8(z = 0) = 0.8$ and a flat Universe, assuming that $\Omega(z) \approx \Omega_{m}(z^{1/3})$. This strongly disagrees with previous constraints made by Planck, that predicts a value of $\Omega_{s8}(z = 0) = 0.315 \pm 0.007$ (Planck Collaboration VI 2018). Hence, the DR14 data does not allow us to broaden the priors too much, as the accuracy is not yet there in the data to rule out cosmological parameters already strongly rejected by Planck measurements.

Fig. A2 shows why this secondary locus is chosen by our MCMC analysis to be an acceptable fit. The blue line is the median of the models of 100 points chosen randomly from the subset of MCMC points within the locus centred around $\alpha \approx 1$ and $\epsilon \approx 0$ ($0 < \alpha < 1$ in Fig. A1). The blue shaded regions indicate the 18th and 84th percentile confidence range. The red line and line-shaded region correspond to models randomly selected from points of our MCMC chain inside locus 2 (top panel of A1).

From Fig. A2 we observe that the best-fitting model within locus 2 do not show a well-defined BAO peak. However, statistically, both sets of models are equally good and indistinguishable in terms of their likelihood. DR15 should have smaller errors around the BAO peaks.

Figure A1. This plot is equivalent to Fig. 17, here we are presenting the MCMC chains of two fits to the RSD-AP parameters in the $\epsilon_0 + \epsilon_2$ space done with different priors in $\epsilon$. The blue solid-line contours use the priors quoted in Table 8 for all parameters but $F_2$ that is set to zero. The red dashed-line contours have larger priors on $\epsilon$ which are expanded to $[-3, 3]$ and also set $F_2$ to zero.
**Figure A2.** This figure shows the median and 1-sigma percentiles for two sets of 100 models built with 100 points chosen randomly from the subset of those explored by our MCMC. The blue shaded regions correspond to points inside the peak centred around the expected cosmology ($\alpha \approx 1$ and $\epsilon \approx 0$). The red line and line-shaded region contours are computed with points inside the second peak that appears for large values of $\epsilon$.

**Figure A3.** This plot is equivalent to Fig. 17, here we are presenting the MCMC chains of two fits to the RSD-AP parameters in the $\xi_0 + \xi_2$ space done with different priors in $\alpha$. The solid-line contours use the priors quoted in Table 8 for all parameters but $F_2$ that is set to zero. The red dashed-line contours have smaller priors on $\alpha$ which are reduced to $[0.9, 1.1]$, and also set $F_2$ to zero.

APPENDIX B: LIKELIHOODS FOR EBOSS SAMPLE USING HEXADECAPOLE

In Section 6.1 we applied our methodology to find the maximum likelihood fits of 84 Nseries high-resolution simulations. We have shown that our methodology provides consistent results with and without hexadecapole information.

As stated in Section 7, we adopted the conservative approach of reporting the $\xi_0 + \xi_2$ as our final result and using the hexadecapole results just as a consistency test. In this appendix, we show results including the hexadecapole.

**Figure B1.** The shaded regions show the $1\sigma$ confidence surfaces found by our MCMC chains for the RSD-AP parameters using $\xi_0 + \xi_2 + \xi_4$ in the $[28, 124] \, h^{-1}$ Mpc range. The red dashed-line contours represent a chain with the priors of Table 8, in the blue solid-line contours the priors in $\alpha$ have been reduced to the interval $[0.88, 1.12]$. The confidence contours for the growth factor $f_{\sigma_8}$, the linear bias $b_{\sigma_8}$, the dilatation parameter $\alpha$, and the warping parameter $\epsilon$ are indicated, along with their 1D distributions. The dashed lines of each histogram are the mean values found by the MCMC chain.
The only difference between both plots are the priors. The red solid-line contours the priors in Table 8, the linear bias $b_{\sigma_8}$ is defined by $b = 1 + F'$. We run two different chains that include $\xi_4$ using the combined data set (NGC + SGC). One using the priors shown in Table 8, and a second chain with more constraining priors. The main reason for this choice is that when considering the priors quoted in Table 8 we find a double peak when fitting the full range, which is shown in Fig. B1. The figure shows the $1-2\sigma$ confidence contours for the growth factor $f_{\sigma_8}$, the linear bias $b_{\sigma_8}$, the dilatation parameter $\alpha$, and the warping parameter $\epsilon$, together with their 1D distributions. The only difference between both plots are the priors. The red dashed-line represent a chain with the priors of Table 8, in the blue solid-line contours the priors have been reduced to the interval [0.88, 1.12]. As discussed in appendix A, this double peaked distribution is a consequence of degenerated solutions not being rejected due to the size of our errors. Following the same procedure done in appendix A we will only analyse the solution that is not in disagreement with mild Planck CMB constraints. In order to try to avoid this second degenerate solution we will reduce the size of our priors in the $\alpha$ parameter to the interval [0.88, 1.12], while the rest of the parameters are fixed to the values of Table 8, these priors were chosen arbitrarily so that they contain the 1-$\sigma$ region of the main peak and completely exclude the second. We acknowledge that it is possible for the statistics obtained from this chain to still be slightly distorted by the presence of this second peak or by the position of the more constrained prior, the reduced error bars of DR16 should make the second peak less significant which could allow us to use larger priors. The statistical results of our parameters are quoted in Table B1: the first line repeats for comparison purposes the results for monopole and quadrupole only ($\xi_0 + \xi_2$). The rest of the table includes the results using monopole, quadrupole, and hexadecapole ($\xi_0 + \xi_2 + \xi_4$). The second line uses the full [28,124] $h^{-1}$ Mpc range in all multipoles. In the last line, the monopole is in the [28,124] $h^{-1}$ Mpc range while the monopole stays in the full range ([24,128] $h^{-1}$ Mpc), the blue solid-line contours show the fit where monopole quadrupole and hexadecapole are in the full range.

![Figure B2](https://example.com/figureb2.png)

**Figure B2.** The shaded regions show the $1-2\sigma$ confidence surfaces found by our MCMC chains for the RSD-AP parameters for two cases: $\xi_0 + \xi_2$ (red dashed-line contours) and $\xi_0 + \xi_2 + \xi_4$ (blue solid-line contours), all multipoles in both models are in the [24,128] $h^{-1}$ Mpc range.

![Figure B3](https://example.com/figureb3.png)

**Figure B3.** Similar to Fig. B2, here the red dashed-line contours represent a fit where the quadrupole and hexadecapole are reduced to the [28,92] $h^{-1}$ Mpc range while the monopole stays in the full range ([24,128] $h^{-1}$ Mpc), the blue solid-line contours show the fit where monopole quadrupole and hexadecapole are in the full range.

### Table B1. Results for the DR14 LRG sample. The first block is for our fiducial methodology, using the fiducial range for the $\xi_0 + \xi_2$ fit. The second block is for the $\xi_0 + \xi_2 + \xi_4$ fits in the ranges [28,124], [28,124], and [44,124] $h^{-1}$ Mpc for their multipoles $l = 0, 2, 4$. The third block is for the $\xi_0 + \xi_2$ and $\xi_0 + \xi_2 + \xi_4$ fits when excluding the large scales for quadrupole and quadrupole/hexadecapole, respectively. The fiducial value for the $\sigma_8 (\xi_{\text{eff}} = 0.72) = 0.55 (0.549532)$. The Eulerian bias is defined by $b = 1 + F'$.

| Case | Measurements with LRG sample DR14 official version |
|------|--------------------------------------------------|
|      | $f_{\sigma_8}$ | $b_{\sigma_8}$ | $\langle F' \rangle$ | $\sigma_{\text{FOG}}$ | $\alpha$ | $\epsilon$ |
| $\xi_0 + \xi_2$ [28,124][28,124] | 0.454$^{+0.119}_{-0.140}$ | 1.110$^{+0.116}_{-0.100}$ | 2.2$^{+3.8}_{-4.4}$ | 3.7$^{+3.0}_{-2.3}$ | 0.955$^{+0.055}_{-0.050}$ | 0.000$^{+0.090}_{-0.050}$ |
| $\xi_0 + \xi_2 + \xi_4$ [28,124] [28,124] [28,124] | 0.31$^{+0.09}_{-0.09}$ | 1.19$^{+0.10}_{-0.10}$ | $-1.1^{+3.2}_{-3.3}$ | 5.8$^{+3.3}_{-3.2}$ | 0.986$^{+0.047}_{-0.046}$ | 0.009$^{+0.046}_{-0.048}$ |
| $\xi_0 + \xi_2 + \xi_4$[28,124][28,92][28,92] | 0.285$^{+0.003}_{-0.004}$ | 1.079$^{+0.108}_{-0.110}$ | $-1.5^{+3.3}_{-3.0}$ | 5.5$^{+2.6}_{-2.8}$ | 0.914$^{+0.054}_{-0.056}$ | 0.100$^{+0.041}_{-0.039}$ |

- $\xi_{\text{eff}} = 0.72$.
[28,124] $h^{-1}$ Mpc range for all multipoles and both chains and they use the priors from Table 8.

Fig. 11 shows that our hexadecapole data have a stronger amplitude on small scales than both sets of mocks. This mismatch in amplitude could be a problem of the mocks or could be due to a real signal in the data, or could be due to either an undetected systematic error in our data or a statistical fluctuation. If it is the latter then the increase in data with DR16 should reduce this shift. If it is a real cosmological signature it should become more significant in DR16. Regardless of the origin of this larger amplitude, the MCMC fitter prefers a large value of $\epsilon$ and a small value of $f \sigma_8$ to fit the amplitude of the data hexadecapole (see Fig. B2).

Fig. B2 shows the results of cutting the large scales for the quadrupole and hexadecapole ($\ell = 2, 4$), the red dashed-line contours come from a chain where the monopole is in the [28,124] $h^{-1}$ Mpc range, and the quadrupole and hexadecapole in the constrained range of [28,92] $h^{-1}$ Mpc. When the last three bins of the quadrupole and hexadecapole are avoided we achieve a significant improvement in the goodness of the fit (we saw this same behaviour in Section 7 when removing the large scales of the quadrupole), we also lose the secondary locus that was present in the full approach without having to reduce our priors; however, the price paid is to eliminate the BAO information. This increases the degeneration of the parameters and biases the results, we lose information that constrains $\epsilon$ and $\alpha$, which in turn causes the contour areas to become larger, providing more freedom to the fitter to move $f$ and $\alpha$ to lower values (Fig. B3).

The main impact of removing the large scales in the hexadecapole fits is in parameters that require the BAO peak to be constrained, as expected. When excluding the large scales, the BAO information is lost, and $\alpha$ is shifted in consequence.
