Time-invariant prefix-free source coding for MIMO LQG control

Travis C. Cuvelier, Takashi Tanaka, and Robert W. Heath, Jr.

Abstract—In this work we consider discrete-time multiple-input multiple-output (MIMO) linear-quadratic-Gaussian (LQG) control where the feedback consists of variable length binary codewords. To simplify the decoder architecture, we enforce a strict prefix constraint on the codewords. We develop a data compression architecture that provably achieves a near minimum time-average expected bitrate for a fixed constraint on the LQG performance. The architecture conforms to the strict prefix constraint and does not require time-varying lossless source coding, in contrast to the prior art.

I. INTRODUCTION

In this work, we consider discrete-time MIMO LQG control where feedback occurs via variable-length packets (codewords) of bits that we assume are conveyed reliably (without error) from a sensor/encoder to a decoder/controller. For some constraint on LQG control performance, we seek to design a sensor/encoder and decoder/controller that minimize the time-averaged expected bitrate of the binary channel.

The motivation for this formulation is communication-efficient remote control over wireless communications. In particular, we imagine a scenario where a remote sensor platform measures some dynamical system and conveys the measurements to the controller over a noisy wireless channel. At the physical and medium access control layers, reliable control of autonomous agents over wireless has motivated the development of ultra low latency reliable communication (ULLRC). While progress has been made on the development ULLRC, the fundamental scarcity of physical layer resources motivates approaches that minimize the use of these resources.

In contrast to the work on ULLRC, we aim higher on the protocol stack; namely we propose to develop control and data compression (source coding) strategies to achieve satisfactory control performance with minimal communication bitrate. The minimum average length, in bits, of the binary packets the sensor encodes are an effective surrogate for the minimum amount of physical layer resources (time/bandwidth/power) required to achieve satisfactory performance for a fixed reliability (cf. e.g. [1, Section 2.6]). We impose a prefix constraint on the codewords that ensures that other users sharing the same communication medium can identify the end of each transmitted message and thus identify the channel as free-to-use. In contrast to the prior art, this work imposes a time-invariant (TI) prefix constraint on the codewords, which simplifies the decoding architecture; the end of codewords can be detected via comparison with a TI list [2].

In the prior literature, achievability results for the problem of interest follow from asymptotically bounding the output entropy of a quantizer [3][4][5]. While these bounds can nearly be achieved with zero-delay lossless source coding, they generally require that the lossless code be adapted, at every timestep, to the probability mass function of the quantizer output (cf. [6, Section IV.A]). This adds a great deal of computational complexity to the encoder and decoder.

In this work, we propose a data compression architecture for MIMO plants based on [4] and [6] that attains the desired LQG performance, satisfies a TI prefix constraint, and does not require a time-varying lossless source codec. Starting from the architecture of [4], we prove that the quantizer output has a limiting distribution. We propose to losslessly encode the quantizations with a fixed prefix-free code adapted the limiting distribution. We prove that under this modification, the codewords satisfy a TI prefix constraint without an increase in codeword length and without the complexity of time-varying lossless source coding. The architecture nearly achieves a known lower bound on the minimum expected bitrate. In particular, we use results from systems theory to extend the scalar TI achievability approach in [6] to the MIMO setting.

A. Related Work

Our work follows from the architecture for LQG control with minimum bitrate prefix-free variable-length coding in [3]. For scalar systems, [3] derived a lower bound on the bitrate of a prefix-free source codec inserted into an LQG feedback channel in terms of Massey’s directed information (DI) [7]. This motivated a rate-distortion problem for the tradeoff between DI and LQG control performance. Using entropy-coded dithered quantization (ECDQ), [3] proved that the DI lower bound was nearly achievable. In ECDQ, uses a shared sequence of IID uniform random variables to whiten the error induced by quantization process. The quantization are then encoded via an entropy source code (e.g. a Shannon–Fano–Elias code). The rate-distortion formulation was generalized to MIMO plants in [8]. Likewise, the achievability approach was generalized in [4]. New analytical lower bounds for the bit-rate/control performance tradeoff were derived in [5]. It was further demonstrated that such bounds were nearly achievable without the use of a dither signal in the high communication rate/strict control cost regime [5]. The achievability approaches in [3], [4], and [5] implicitly assume that quantizations are encoded using a time-varying lossless source code [6]. More recently, [9] and [2] refined the lower
bound analysis in [3], clarifying that the bound still applies even when the encoder and decoder share a dither signal.

The use of time-varying source codes complicates compression architectures; generally speaking, the codebooks used to encode quantizations must be updated at every timestep. Furthermore, in network settings, a source code’s prefix properties may be used by receivers to detect the end of transmissions. If a TI prefix code is used, the set of prefixes against which received codewords are compared is constant over time [2]. In the time-varying case, there are no such guarantees. In [6] it was shown that when a dither signal is available, there exists a TI quantization and coding scheme for scalar plants that nearly achieves the DI lower bound. In this work, we generalize this to the MIMO setting; namely we prove the existence of a quantizer and TI source codec for MIMO plants that nearly achieves the directed information lower bound [8]. We believe this to be the first such “time-invariant” achievability result for MIMO plants in the literature.

Work on fixed bitrate and event-driven communication strategies for control are also relevant to this work. In [10], numerical experiments demonstrated that Lloyd-Max style quantization could be used to attain a control performance competitive with known variable-rate upper bounds. However, the quantizer in [10] is time-varying, and many experimental realizations had time-average control costs that greatly exceeded the variable-length bounds [10]. More recently, [11] have proposed the mean time to quantizer saturation as a metric for the analysis of fixed-length coding in LQG feedback control. Periodic coding strategies were devised, and their performances and escaped times were analyzed theoretically and with an experiment [11]. More recently [12] considered tracking a scalar Markov source under an event-based communication paradigm. Under this formulation, an encoder monitoring a plant can send binary codewords (without prefix constraints) at arbitrary (continuous-time) instants to a synchronized decoder [12]. For a constraint on estimator error, the minimum bitrate communication policy was deduced. In this work, as in [4], [5], [10], we consider a sampled discrete-time control and communication model. While event-driven schemes like [12] may be able to achieve smaller bitrates than these works, the models for control and communication in [4], [5], [10] are more amenable to real-world sampled data systems with finite sensing and communication bandwidths.

B. Notation

We denote constant scalars and vectors in lowercase \( x \), scalar and vector random variables in boldface \( \mathbf{x} \), and matrices by capital letters \( X \). We let \( [x]_i \) denote the \( i \)th element of \( x \), \( I_m \) denote the \( m \times m \) identity matrix, \( 0 \) \( m \) the respective zero matrix. Let \( X \) denote the largest singular value of \( X \). We write \( P(S)D \) for “symmetric positive (semi)definite”, and let \( S_{+}^m \) denote the set of \( m \times m \) PSD matrices. We let \( A \) \( B \) denote the standard partial order on the PSD cone, e.g., if \( A \) \( B \) \( \mathbb{R}^m \), we write \( A \preceq B \) if \( A - B \) is PSD. Likewise \( A \prec B \) if \( A - B \) is PSD. For time domain sequences, let \( x_t \) denote \( (x_0, x_1, \ldots) \), \( x_a^b \) denote \( (x_a, \ldots, x_b) \) if \( a \), \( x_a^b = x_a \) otherwise. Let \( x^\Delta = x^\Delta_0 \). Denote the set of finite-length binary strings by \( 0, 1 \). For \( \alpha \), \( 0, 1 \), let \( \ell(\alpha) \) be the length of \( \alpha \) in bits. Let \( \Delta_{m}^Z \) denote the set of \( m \) tuples whose elements are integer multiples of \( \Delta \). Define the set \( B_{m}^*(D) = x \mathbb{R}^m : x \mathcal{D}^Z \). For a set \( S \), define the indicator function of \( x \) \( S \) as \( 1_{x \in S} \). For a topological space \( \mathcal{T} \), let \( B(\mathcal{T}) \) denote the standard Borel \( \sigma \)-algebra of \( \mathcal{T} \). For Euclidean spaces, let \( \lambda \) denote the Lebesgue measure. We use PMF for “probability mass function”, PDF for “probability density function” (with respect to \( \lambda \)), \( a \preceq b \) for “\( a \) and \( b \) are independent”, and \( H \) for entropy.

II. SYSTEM MODEL AND PROBLEM FORMULATION

We consider the system model depicted in Fig. 1. The system to be controlled is a TI, multidimensional, linear dynamical system (i.e., a MIMO plant) plant controled via a feedback model where communication occurs over an ideal (delay and error free) binary channel. The plant is fully observable to an encoder/sensor block, which conveys a variable-length binary codeword \( \alpha \), \( 0 \) from the channel to a combined decoder/controller. Upon receipt of the codeword, the decoder/controller designs the control input. Denote the state vector \( x_t \mathbb{R}^m \), the control input \( u_t \mathbb{R}^m \), and let \( w_t \mathcal{N}(0, W) \) denote processes noise assumed to be IID over time. We assume \( W = 0 \) \( m \times m \), i.e., the process noise covariance is full rank. We assume that \( x_0 \mathcal{N}(0, X_0) \), and that the sequence \( d_t \) is IID over time. We assume \( A = 0 \) \( 0 \), \( d_t \), and \( x_0 \) are mutually independent. In real-world systems, this shared randomness can be effectively accomplished using synchronized pseudorandom number generators. We assume that the encoder/sensor and the decoder/controller may be randomized given their inputs. The encoder/sensor policy in Fig. 1 is a sequence of causally conditioned Borel measurable kernels denoted \( P_E[a_x d_t x_0] = \{ P_E[a_x a_0^t d_t x_0^t] \} \), and that corresponding decoder/controller policy is given by \( P_C[u a d u w x_0] = \{ P_C[u a^t d^t u^t w^t] \} \). Note that under the assumed dynamics, \( u^t \) and \( d^t \) are independent. The sequence \( d_t \) is IID over time. We assume \( u_t \mathcal{N}(0, W) \) and \( x_0 \mathcal{N}(0, X_0) \) are mutually independent. In real-world systems, this shared randomness can be effectively accomplished using synchronized pseudorandom number generators. We assume that the encoder/sensor and the decoder/controller may be randomized given their inputs. The encoder/sensor policy in Fig. 1 is a sequence of causally conditioned Borel measurable kernels denoted \( P_E[a_x d_t x_0] = \{ P_E[a_x a_0^t d_t x_0^t] \} \), and that corresponding decoder/controller policy is given by \( P_C[u a d u w x_0] = \{ P_C[u a^t d^t u^t w^t] \} \). Note that under the assumed dynamics, \( u^t \) and \( d^t \) are independent. The sequence \( d_t \) is IID over time.
and that we have initially \( P[a_0, d_0, u, w_0 x_0] = P[w_0]P[d_0]P_E[a_0 x_0, d_0] P_C[u_0 a_0, d_0] \). Implications of these factorizations are discussed in the caption of Fig. 1.

We require the codewords to conform to a TI prefix constraint, namely that for all \( i, j \) and distinct \( a_1, a_2 \), with both \( P[a_i = a_1] > 0 \) and \( P[a_j = a_2] > 0 \), \( a_1 \) is not a prefix of \( a_2 \) and vice-versa. Thus, not only must the support of the random variable \( a_i \) be a set of prefix-free binary codewords, we also require the union of the supports of the \( a_i \) to be prefix-free. This is a stronger prefix constraint than was considered in [4]. The TI constraint may enable for more computationally efficient communication resource sharing; the end of a codeword can be unambiguously identified via comparing received messages against the TI union of supports. We are interested in the following optimization, over policies \( P_E, P_C \) that conform to the prefix constraint:

\[
\mathcal{L}(\gamma) = \inf_{P_E, P_C} \frac{1}{\mathcal{T}} \sum_{t=0}^{\mathcal{T}-1} \mathbb{E}[\ell(a_t)]
\]

\[
\text{s.t. } \frac{1}{\mathcal{T}} \sum_{t=0}^{\mathcal{T}-1} \mathbb{E}[\|x_{t+1} - \hat{x}_t\|_2^2 + u_t \|u_t\|_2^2] \leq \gamma,
\]

where \( \gamma \) is the maximum tolerable LQG cost. Let \( S \) be a stabilizing solution to the discrete algebraic Riccati equation (DARE) \( A^T S A - S + A^T S B (B^T S B + \Phi)^{-1} B^T S A + Q = 0 \), \( K = (B^T S B + \Phi)^{-1} B^T S A \), and \( \Theta = K^T (B^T S B + \Phi) K \). Consider the optimization

\[
\mathcal{R}(\gamma) = \inf_{P_{II}, P} \frac{1}{\mathcal{T}} \sum_{t=0}^{\mathcal{T}-1} \left( - \log_2 \text{det} \Pi + \log_2 \text{det} W \right)
\]

\[
\text{s.t. } \text{Tr}(\Theta P) + \text{Tr}(W S) \leq \gamma,
\]

\[
P = APA^T + W,
\]

\[
[ P - \Pi \quad \Pi P^T \quad AP \quad APA^T + W ] \geq 0.
\]

A consequence of [2] (cf. [6] and [8]) is the lower bound \( \mathcal{R}(\gamma) \geq \mathcal{L}(\gamma) \). In the sequel, we will analyze the bitrate of the proposed achievable scheme in terms of \( \mathcal{R}(\gamma) \).

### III. Achievability Architecture

The achievability approach we proposed is demonstrated in Fig. 2. It is almost identically to the time-varying MIMO achievable approach in [6, Section IV.B] with the exception that the lossless Shannon–Fano–Elias source code used to encode the quantizations is TI. We first describe the signals in Fig. 2 before summarizing relevant results from [6] that simplify the analysis. Let \( \hat{P} \) denote the minimizing \( P \) from (3), let \( \hat{P}_t = AP \hat{A}^T + W_t \), and let \( \Delta \in \mathcal{F} \Delta, \Delta > 0 \), and \( C \in \mathbb{R}^{\mathcal{M} \times \mathcal{M}} \) be such that \( \hat{P}_t^{-1} - \hat{P}_t = C^T C \Delta^{-2} \). In this way, \( \hat{P}_t (\hat{P}_t) \) is interpreted as the asymptotic (prediction) error covariance attained by a Kalman filter tracking the source process \( x_t \) under a measurement model \( y_t = C x_t + v_t \), where \( \mathbb{E}[v_t x_{t+k}^T] = I_m \Delta_s^2 \mathbb{1}_{k=0} \). We will show that this measurement model is attained by the decoder in Fig. 2 using dithered quantization.

![Fig. 2. The achievable architecture. Descriptions of the variables may be found in Table I.](image)

**Table I**

| Variable | Description/Key Equations |
|----------|---------------------------|
| \( P \) \( \mathbb{S}^m \) | Minimizing \( P \) of (3), asymptotic KF estimator error |
| \( P_t \) \( \mathbb{S}_+^m \) | \( P_t = AP \hat{A}^T + W_t \), asymptotic KF prediction error |
| \( C \) \( \mathbb{R}^{\mathcal{M} \times \mathcal{M}} \) | Measurement matrix, \( P_t^{-1} - P_t = C^T C \Delta^{-2} \) |
| \( \Delta \) \( \mathbb{R} \) | Quantizer/dither sensitivity, \( P_t^{-1} - P_t = C^T C \Delta^{-2} \) |
| \( K \) \( \mathbb{R}^{\mathcal{M}} \) | Certainty equivalent feedback control gain |
| \( \hat{F}_{t-1} \) \( \mathbb{R}^m \) | TI KF prediction of \( x_t \) |
| \( \hat{F}_{t-1} \) \( \mathbb{R}^m \) | TI KF estimate of \( x_t \), \( u_t = K \hat{F}_{t-1} \) |
| \( \hat{P}_t \) \( \mathbb{R}^m \) | KF predict error \( \hat{P}_t = \hat{F}_{t-1} x_t \) |
| \( \hat{P}_t \) \( \mathbb{R}^m \) | Dither sequence, IID elements \( \text{Uniform}(\Delta) \) |
| \( q_t \) \( \mathbb{R} \) | Quantization \( q_t = Q_\Delta (C x_t + d_t) \), encoded into \( \hat{a}_t \) |
| \( \hat{q}_t \) \( \mathbb{R} \) | Reconstruction \( \hat{q}_t = \hat{q}_t - d_t \), error \( v_t \) |
| \( \hat{F}_{t-1} \) \( \mathbb{R}^m \) | Reconstruction \( \hat{q}_t = \hat{q}_t - d_t \), error \( v_t = \hat{q}_t - C \hat{F}_{t-1} \) |
| \( \hat{F}_{t-1} \) \( \mathbb{R}^m \) | Effective measurement at decoder \( \hat{F}_{t-1} = C \hat{x}_t + v_t \) |
recover \( q_t \) exactly. It then produces the reconstruction \( \tilde{q}_t = q_t \). Let \( v_t = \tilde{q}_t \). Define the encoding function \( \tilde{q}_t = \hat{q}_t = Cx_t + v_t \). By [4, Lemma 1], the elements \([v_t]_i\) are mutually independent and uniform on \([\Delta/2, \Delta/2]\) and furthermore \( v_t \) are mutually dependent on \( x_t \). Denote the TI Kalman filter gain 
\[
J = \hat{P}_n C^T (C \hat{P} + C^T + \begin{pmatrix} \Delta/2 & \Delta/2 \end{pmatrix})^{-1}.
\]

The decoder updates its estimate via
\[
\tilde{x}_{t+1} = \tilde{x}_t + J(v_t - \tilde{q}_t)
\]
and applies the certainty equivalent control input \( u_t = K \tilde{x}_t \). It then computes the predict estimate \( \tilde{x}_{t+1} = A \tilde{x}_t + B u_t \). Since the encoder knows the quantizations \( \hat{q}_t \) and the dither \( d_t \), it can recover the sequence of measurements \( y_t \). The encoder can thus compute the sequence of TI Kalman filter estimates \( \tilde{x}_{t+1}, \tilde{x}_{t+1} \). While we have yet to define how \( q_t \) is encoded into \( a_t \), we have the following.

**Lemma 1:** So long as the decoder recovers \( q_t \) exactly at every \( t \), we have that 1) \( v_t = q_t + \delta_t \), \( 0 < \delta_t \leq 1 \), \( 2) \lim_{t \to \infty} \mathbb{E}(\delta_t) = \delta_0 \leq 1 \), \( 3) \lim_{t \to \infty} \sum_{i=0}^t \mathbb{E}(\delta_t) = \delta_0 \leq 1 \).

The first statement follows from [4, Lemma 1] and the system model and the subsequent are via [6, Theorem IV.5].

The TI prefix constraint can be satisfied by encoding each \( q_t \) with the same lossless prefix code at all time. Let \( q \) be a discrete random variable on \( \Delta^m \) (the same alphabet as \( q_t \)). Assume the support of \( q \) is such that \( \mathbb{P}[q = k] = 0 \) only if \( \mathbb{P}[q = k] = 0 \). Define \( C^q(q) = q \). Define the encoding function \( C^q(q) : \Delta^m \to \mathbb{R}^m \) such that \( C^q(q) = \binom{q}{1:2} \) truncated to \( \log_2(\binom{q}{1:2}) \) + 1 bits. This is a standard, lossless, prefix-free Shannon-Fano-Elias code for the random variable \( q \) [13]. If we use \( C^q \) to encode \( q_t \), we have the following lemma, proved in Section IV.

**Lemma 2:** There exists a random variable \( q \) such that \( D_{KL}(q, q) \) is finite for all \( t \) and \( \lim_{t \to \infty} D_{KL}(q_t, q) = 0 \). This lemma allows us to bound the bitrate for when a TI prefix-free code is used in Fig. 2.

**Theorem 3:** Let \( \eta = \frac{1}{2} \log_2(\frac{2\Delta}{\Delta^m}) \). Setting \( a_t = C^q(q_t) \) for all \( t \) ensures that the system in Fig. 2 attains a cost control less than \( \gamma \), satisfies the prefix constraint in Section II, and attains a communication cost that satisfies
\[
\limsup \frac{1}{T} \sum_{i=0}^T \mathbb{E}(\ell(a_t)) \mathbb{E}(\gamma) + 2 + m \eta
\]

**Proof:** \( C^q \) is a prefix free code fixed over all \( t \). Furthermore, since \( D_{KL}(q_t, q) \) is finite for all \( t \), it is lossless on the support of \( q_t \). The bound on codeword length (7) follows via applying (6) to each term on the left-hand side and then using the Cesàro mean (cf. Lemma 1). □

In Section IV, we use ergodic theory to prove Lemma 2.

**IV. PROOF OF LEMMA 2**

We proceed as in [6] by analyzing the long-term behavior of the Kalman innovation and dither signals, e.g. \( (e_t, d_t) \). At every \( t \), the quantization error \( v_t \) is a measurable function of \( (e_t, d_t) \) given by \( v_t = q_t \). Let \( L = A \) and \( R = A = LC \). The following recursion for the \( e_t \) (cf. (4)) can be derived
\[
e_{t+1} = Re_t \frac{L}{v_t + w_t}
\]

By construction of \( L \), \( (A = LC) \) is stable, e.g. its eigenvalues lie strictly within the complex unit circle [14]. Define the state space \( D^m = \mathbb{R}^m \mathbb{B}^m(\Delta) \). For \( (r, \mu) \in D^m \) and \( \Sigma \in \mathbb{S}^m \), denote the PDF of a multivariate Gaussian random variable with mean \( \mu \) and covariance \( \Sigma \) evaluated at \( r \) by \( N(r; \mu, \Sigma) \), i.e. define the function \( N(r; \mu, \Sigma) : \mathbb{R}^m \to \mathbb R^m \) via \( N(r; \mu, \Sigma) = \frac{1}{(2\pi)^m \det \Sigma} e^{\frac{1}{2}(r - \mu)^T \Sigma^{-1} (r - \mu)} \). Define \( M : (x, y) \to \mathbb{R}^m \) via \( M(x, y) = Rx + LQ \Delta(Cx + y) \). By construction, the marginal PDF of the dither is \( f_{d_t} = \frac{1}{(2\pi)^m \det \Sigma} e^{\frac{1}{2}(x - \mu)^T \Sigma^{-1} (x - \mu)} \). Let \( f_{t+1} = f_{t+1, t} \). The PDFs of \( e_t, d_t \) factorize via \( f_{t+1} = f_{t+1, t} f_{t+1, t} \). From the foregoing, we have
\[
e_{t+1} = R \frac{L}{v_t + w_t}
\]

Applying the Chapman-Komogorov equations to (12), it can be seen that the \( n \)-step transition kernels satisfy
\[
e_{t+n} = \frac{1}{(2\pi)^m \det \Sigma} e^{\frac{1}{2}(x - \mu)^T \Sigma^{-1} (x - \mu)}
\]

We now state the generalization of [6, Lemma A.3].

**Lemma 4:** Let \( \mu_n = \sum_{i=0}^n R_i W_i \) hold for \( n = 1 \). Assume that the relation (14) holds for some \( n = k \). To avoid clutter, when obvious we suppress the arguments to PMFs, writing, e.g. \( f_{e_k} e_0, d_0, v_{k-1} \) in place of \( f_{e_k} e_0, d_0, v_{k-1} \). Via Bayes Theorem,
Using Lemma 5, it is seen that for some $W$.

**Proof:** The first statement is immediate from the assumption

and the formula for $\Sigma_k$ the convolution, we have

As $w_k$, $e_k$, $e_0$, $d_k$ are independent, we have, via (8) that $e_k$ is conditionally independent of $(e_0, d_k)$. Thus $f_{v_k} e_k e_k - e_0 d_k v^{k-1} = f_{v_k} e_k e_k e_0 d_k v^{k-1} - f_{v_k} e_k e_0 d_k v^{k-2} d e_k$. This further implies that $v_k$ is independent of $(v_{k-1} e_0 d_k)$. Thus we have

Using (15), it can be seen that $f_{e_k} e_k e_0 d_k v^{k-1} f_{v_k} e_k e_0 d_k v^{k-1} - f_{v_k} e_k e_0 d_k v^{k-2} d e_k$. Thus,

The next lemmas describe properties of $\Sigma_n$ and the sequence of functions $\mu_n(e_0, d_0, v_0)$. We recall a result from system theory.

**Lemma 5** (Gelfand’s Theorem and a Corollary [15]): Let $Q$ and denote the spectral radius of $Q$ (e.g. the largest of the absolute values of $Q$’s eigenvalues) by $\rho_{\max}(Q)$. Gelfand’s Theorem states that $\lim_n Q^n \to \rho_{\max}(Q)$. Let $\gamma = (\rho_{\max}(Q) + 1)/2$. If $\rho_{\max}(Q) < 1$ then $\gamma < 1$ and by Gelfand’s Theorem $i$ such that $j i \notin \rho_{\max}(Q)$.

**Lemma 6:** We have $\Sigma_n < 0 m^2$. Furthermore, there exists a constant $c$ such that for all $n$, $\Sigma_n \geq c$.

**Proof:** The first statement is immediate from the assumption that $\Sigma_n < 0 m^2$ and the formula for $\Sigma_n$ in Lemma 4. Note that since $\Sigma_n \geq 0$ and $\Sigma_n$ is monotonically increasing. Recall that $\rho_{\max}(R) < 1$ [14]. Using Lemma 5, it is seen that for some $c < 1$,

$\lim_n \sum_{i=0}^{\infty} R^i 2^c W = c$. The triangle inequality and the submultiplicativity of the matrix 2-norm gives $\Sigma_n = \Sigma_n 2 c$.

**Lemma 7:** There exist constants $\alpha$ and $\beta$ such that for any $n$ and choice of $v_0, v_1^{n-1}$, $R^{m(n)}$ we have $\mu_n(e_0, d_0, v_0) \geq 0$ and $\mu_n(e_0, d_0, v_1^{n-1}) \geq 0$. We use the fact that for $v_j$, $B^{m(n)}(\Delta)$, $v_j \geq 0$, $\Delta = \frac{m}{2}$.

For $\alpha$, $\beta$, and $c$ as defined in Lemmas 6 and 7, define a subset of $\mathbb{R}^m$ $\mathbb{R}^m$ via $\mathcal{M}(e_0, d_0, m, L, R, \Delta) = (\mu, \Sigma) \in \mathbb{R}^m$ $\mathbb{R}^m = \mu_2 = \alpha \mathcal{M}(e_0, d_0) + \beta, \Sigma W, \Sigma_2 \frac{m}{2}$. We have that $\mathcal{M}(e_0, d_0, m, L, R, \Delta)$ is compact (closed and bounded). This helps prove the main result of this section.

**Lemma 8:** There exists an invariant PDF $g$ such that

and $g(x, y) > 0$ for all $(x, y) \in \mathbb{D}$. A consequence of [16, Theorem 5] is that there exists an invariant PDF $g$ satisfying (18) and $g(a, b) > 0$ for all $(a, b) \in \mathbb{D}$ if and only if every weakly transient set $F$ has $\lambda(F) > 0$. To prove the lemma, we proceed via contradiction. We prove that any set $F \in \mathbb{D}$ with $\lambda(F) > 0$ is not weakly transient. Let $F \subseteq \mathbb{D}$ have $\lambda(F) > 0$. Since $\lambda(F) > 0$, $F$ must contain an open ball, which in turn must contain a closed rectangle of positive Lebesgue measure, e.g. there exists a $\delta > 0$ and point $(e_F, d_F)$. $F$ such that the set $H = (x, y) \in \mathbb{R}^m$ $\mathbb{R}^m : x e_F \in [\delta, 1/2], y d_F \in [1/2, \delta]$. $H$ has $H F$. Note $\lambda(H) = \delta 2^m$. Define the “$\delta$-section” of $H$ as the subset $H_{\delta} \subseteq x \in \mathbb{R}^m$ $: x e_F \in [\delta, 1/2]$. As $H F$, the conditional probability satisfies

Since the “minimum is less than the average”, we have

Using the explicit formula for $f_{e_n, e_0, d_0, v_0^{n-1}}$ given by (14) in Lemma 4, the right side of (21) can be written in terms of $\Sigma_n$ and $\mu_n(e_0, d_0, v_0^{n-1})$. However, for a fixed $(e_0, d_0)$, Lemma 7 proves a compact set that contains $\mu_n(e_0, d_0, v_0^{n-1})$ for any choice of $n$ and $v_0^{n-1}$. This set is given by $C_\mu = \mu_2 = \alpha \mathcal{M}(e_0, d_0) + \beta$. Likewise, for any $n_i$, $\Sigma_n$ falls within the compact set $C_\Sigma = \Sigma \mathbb{R}^m : \Sigma W, \Sigma_2 \frac{m}{2}$. Thus, we have, for any $n_i$

\[ \inf_{x H_{\Sigma}} f_{e_n, e_0, d_0, v_0^{n-1}}(x e_0, d_0, v_0^{n-1}) \]
Note that the optimization on the right of (22) does not depend on \( n_i \). At every point \((x, \mu, \Sigma)\) where \( \Sigma \neq 0 \), the positive function \( N(x; \mu, \Sigma) \) is continuous. Note that the subset \( H_{\epsilon} C_{\epsilon}, C_{\Sigma} \) is closed and bounded, thus compact, and that \( \Sigma \subset C_{\Sigma} \). Thus we have that there exists \( \epsilon > 0 \) such that \( \lim_{x} H_{\epsilon}, C_{\epsilon}, \Sigma C_{\Sigma} N(x; \mu, \Sigma) = \epsilon \). Thus, following the inequalities from (20) through (22) gives, for any \( n_i \), that \( \mathbb{P}_{e_{n_i}} d_{o_{0}} [F_{c_{0}} d_{0}] > \epsilon \). Thus for any \( F \) with \( \lambda(F) > 0 \) the terms in the summation (19) are bounded from below by \( \epsilon \). For any subsequence \( n_i \) of \( N \) the summation in (19) diverges, which implies \( F \) is not weakly transient. Thus, if \( F \) is weakly transient, it must have \( \lambda(F) = 0 \), which via [16, Theorem 5] proves the lemma.

The next ensures that the sequence \( e_t, d_t \) converges to \( g \).

**Lemma 9:** Let \( (e, d) \to g \) and \( (e_0, d_0) \) be drawn from a continuous distribution on \( D \). The sequence of random variables \((e_t, d_t)\) converges weakly to \((e, d)\).

**Proof:** We can prove this result using [17, Theorem 4] adapted to the special case when a first-order time-homogeneous Markov chain admits an invariant PDF (18) (in other words, when the chain admits an invariant measure that is absolutely continuous with respect to Lebesgue measure). A Markov chain \( g_t \) on a state-space \( G \) is said to be \( \phi \)-irreducible if there exists a nonzero \( \phi \)-finite measure \( \phi \) such that for all measurable \( \mathcal{G} \) with \( \phi(\mathcal{G}) > 0 \) and all initial conditions \( z_0 = z_0 \in \mathcal{G} \) we can find an integer \( n \) such that \( \mathbb{P}_{z_n} z_0 > 0 \). A Markov chain \( g_t \) on \( G \) is aperiodic if there does not exist \( d \neq 1 \) and disjoint nonempty measurable subsets \( g_0, g_1, \ldots, g_d \) such that when \( g_n = g_i \), then \( \mathbb{P}_{g_n} g_{n+1} = 1 \). A consequence of [17, Theorem 4] is that if the Markov chain \( g_t \) admits an invariant PDF \( g \), is \( \phi \)-irreducible, aperiodic, and \( e_0 \) is a continuous random variable then the \( g_t \) converge weakly to the measure induced by the invariant PDF. Consider the Markov chain \( e_t, d_t \) on \( D \), and recall that the Lebesgue measure \( \lambda \) on \( D \) is countably generated. Take \( \mathcal{A} \) with \( \lambda(\mathcal{A}) > 0 \) and let \( (e_0, d_0) \in \mathcal{A} \) be arbitrary. We have

\[
\lim_{t \to \infty} \mathbb{P}_{e_t, d_t} [e_{0} d_{0} | e_{0}, d_{0}] = \int_{\mathcal{A}} 1_{f_{t+1} e, d} d \lambda(e, d) \, dd. \tag{23}
\]

It is immediate from the definition of \( f_{t+1} e, d \) in (12) and the fact that \( \mathcal{A} \in \mathcal{D} \) that \( \mathbb{P}_{e_t, d_t} [e_{0} d_{0} | e_{0}, d_{0}] \to 0 \). Thus the Markov chain \( e_t, d_t \) is \( \lambda \)-irreducible.

Via the same logic, it can be shown by contradiction that the chain is aperiodic. Assume that the chain is periodic, e.g., that for \( d = 2 \), there exist disjoint nonempty measurable subsets \( A_0, A_1, \ldots, A_2 \) \( \mathcal{D} \) satisfying such that if \( e_n, d_n \) \( A_i \) then \( \mathbb{P}_{e_{n+1}, d_{n+1}} [(e_{1}, d_{1}) A_{i} | e_n, d_n] \). Assume that \( A_i \) has \( \lambda(A_i) > 0 \) (since the sets \( A_k \) partition \( \mathcal{D} \), at least one of them must have positive Lebesgue measure). Take \( (e_1, d_1) \) \( A_i \), and let \( j = i + 1 \mod d \). By the assumption of periodicity

\[
\mathbb{P}_{e_{t+1}} [(e_{t+1}, d_{t+1}) A_j (e_t, d_t) = (e_t, d_t) = 1. \tag{24}
\]

If \( A_i \) has \( \lambda(A_i) > 0 \), for any \( (e_t, d_t) \) our proof of irreducibility guarantees that \( \epsilon > 0 \) such that \( \mathbb{P}[(e_{t+1}, d_{t+1}) A_i e_t = e_t, d_t = d_t] \). As we assumed \( A_i A_i = \), this contradicts (24). Thus the Markov chain \( e_t, d_t \) is aperiodic, and by [17, Theorem 4] we have the proof.

The next lemma characterizes the invariant PDF \( g \).

**Corollary 10:** Assume \( (e, d) \to g \). Denote the marginal PDF of \( e \) by \( g \). We have that \( e, d \) \( \mathcal{D} \). Uniform [\( \Delta/t, \Delta/2] \). This implies that \( g : \mathcal{D} \to \mathcal{R} \) factorizes via \( g(e, d) = g_\infty(e)/\Delta^t \) for \( e, d \).

**Proof:** Let \( A_i \) be an open ball in \( \mathcal{R} \) and \( A_2 \) be an open ball inside \( \mathcal{R} \). Open intervals like \( A_1 \) \( A_2 \) form a \( \mathcal{P} \) system that generates the \( \sigma \) algebra \( \mathcal{B}(\mathcal{D}) \). Using the definition of the transition kernel (12) and the invariant PDF (18), it can be shown that \( \mathcal{P} = A_1 A_2 \) then \( \mathbb{P}[(e, d) \in \mathcal{P}] = \int_{A_\infty} g_\infty(e)de \lambda(\mathcal{A}) \). By Dynkin’s \( \lambda \) theorem, this proves that \( e, d \) (see e.g., [18, Prop. 2.13]).

**Lemma 11:** \( D_{KL}(q_t, q) < \infty \) and \( \lim_{t \to \infty} D_{KL}(q_t, q) = 0 \).

**Proof:** Using the properties of the invariant measure and a data processing inequality for \( f \)-divergences ([19, Theorem 2.2] (6)) one can prove that the sequence of relative entropies is monotonically decreasing, i.e., that \( D_{KL}(q_t, q) \to 0 \) for all \( t \). Since \( D_{KL}(q_t, q) \), the limit as \( t \) exists. From applying the data processing inequality for KL divergences several times (cf. [19, Theorem 2.2] (6) ), and the fact that both \( d_t, e_t \) and by Corollary 10 that both \( e, d, d_t \) and \( d_t \) are identically distributed, we have that \( D_{KL}(q_t, q) = D_{KL}(e_t, e) \). Details can be found in the proof of [6, Lemma IV.10]. The rest of the proof follows from bounding \( D_{KL}(e_t, e) \).

Let \( \nu_t \) denote an IID sequence of random variables uniformly distributed on \( B^\infty(\mathcal{D}) \). Likewise, let \( \omega_t \) be IID with \( \omega_t \in \mathcal{N}(0, W) \), and let \( \lambda \in \mathcal{N}(0, X_0) \). Assume \( \omega_t, \nu_t, \lambda \) are mutually independent. Let \( a \equiv b \) denote \( a \) and \( b \) are identically distributed. By unwrapping the recursive definition of \( e_t \) in (8), we have \( e_t = R^t \lambda + \sum_{i=0}^{t-1} R \nu_i \). Likewise, by definition of \( e \), we have that \( e_t = \lim_{t \to \infty} R^t \lambda + \sum_{i=0}^{t-1} R^t \lambda \nu_i \) and \( e = \lim_{t \to \infty} R^t \lambda \nu_t = \sum_{i=0}^{t-1} R^t \lambda \nu_t \). Note that the limit in the definition of \( \nu_t \) is well defined via Lemma 5 in concert with Kolmogorov's two-series theorem. By definition, \( e_t = R^t \lambda + \nu_t \) and \( e = \nu_t \). Note that \( g_t \) \( \mathcal{N}(0, \sum_{i=0}^{t} \mathcal{R}^t \mathcal{R}^t) \). We have

\[
D_{KL}(e, e) \leq D_{KL} (R^t \lambda + g_t, g_t + s_{t+1}) \tag{25}
\]

\[
D_{KL} (R^t \lambda + g_t, g_t + s_{t+1} s_{t+1}) \tag{26}
\]
f-divergences and (26) follows since conditioning increases KL divergence (see [19, Theorem 2.2 (5)]). Given $s_{t+1} = s_t$, (26) simplifies to a KL divergence between multivariate Gaussians. Let $S_t = \sum_{i=0}^{t} R W R^T$ and $\tilde{S}_t = S_t + R^T X_0 (R^T)^t$. Since $\lambda > g_t$ by construction, $R^T \lambda + g_t N(0, \tilde{S}_t)$. Recall also that $g_t s_{t+1}$ by construction. We have then that $D_{KL}(R^T \lambda + g_t N(0, \tilde{S}_t)) = D_{KL}(N(0, \tilde{S}_t))$. Let $f_t : \mathbb{R}^m \mapsto \mathbb{R}^m$ be defined via

$$f_t(s) = \text{Tr}(S_t^{-1} \tilde{S}_t) + s^T S_t^{-1} s + \ln(\det S_t/\det \tilde{S}_t).$$

(27)

We have that $D_{KL}(N(0, \tilde{S}_t)) = \frac{1}{2} f_t(s)$, where the divergence is expressed in nats. Thus, via (26),

$$D_{KL}(q_t, \tilde{q}_t) = \frac{1}{2} \mathbb{E}[|f_t(s)|] m.$$

(28)

Since $s_{t+1} \in \mathbb{L}^2$ and $S_t, \tilde{S}_t \in \mathbb{L}$, it is clear that the right-hand side of (28) is finite for all $t$. We now demonstrate that $\lim_t \mathbb{E}[|f_t(s)|] = 0$, attaining the terms in (27) one-at-a-time. As $\tilde{S}_t$ and $S_t$, $W, 0 m, m$, the determinants $\det S_t$ and $\det \tilde{S}_t$ are bounded strictly away from 0. Since $\rho_{\max}(R) < 1$, we have that $Q = \lim_t S_t$ is well defined, and that $\lim_t \tilde{S}_t = Q$. Thus

$$\lim_t \ln(\det S_t/\det \tilde{S}_t) = 0$$

and

$$\lim_t \text{Tr}(S_t^{-1} \tilde{S}_t) = m.$$

We now prove $\lim_t \mathbb{E}[s^T S_t^{-1} s] = 0$. Fix $t$ and let $\rho_{\max}(R) = \sum_{i=0}^{t} R^i (\omega_i L U_j)$. For any $t$, $\lim_r \rho_{\max}(R) = s_t s_t^T$. These limits are well defined by Kolmogorov’s two-series theorem. Let $U = W + L^\Delta T^T L T$. Theorem 5. Let $\mathbb{E}[s^T S_t^{-1} s] = \mathbb{E}[\text{Tr}(S_t^{-1} s_t s_t^T)]$. Then $\mathbb{E}[s^T S_t^{-1} s_t s_t^T] = \lim_r \inf_r \mathbb{E}[p_t p_t^T]$. These limits are well defined by Kolmogorov’s two-series theorem. Let $U = W + L^\Delta T T^T l T$. We have

$$\mathbb{E}[s^T S_t^{-1} s_t s_t^T] = \mathbb{E}[\text{Tr}(S_t^{-1} s_t s_t^T)]$$

(29)

where (30) follows from Fatou’s lemma, and linearity. We have $\mathbb{E}[p_t p_t^T] = \sum_{i=0}^{t} R^i U (R^i)^T$, thus

$$\lim_r \mathbb{E}[p_t p_t^T] = R^i \left( \lim_r \sum_{i=0}^{t} R^i U (R^i)^T \right) (R^i)^T,$$

where the limit exists via Lemma 5. Let $N = \left( \lim_r \sum_{i=0}^{t} R^i (W + L^\Delta T T^T l T) (R^i)^T \right)$. We have established that $\mathbb{E}[s^T S_t^{-1} s_t s_t^T] = \text{Tr}(S_t^{-1} R^i N (R^i)^T)$. Since $\rho_{\max}(R) < 1$ taking the limit as $t$ proves $\lim_t \mathbb{E}[s^T S_t^{-1} s_t s_t^T] = 0$. Thus, in conclusion

$$\lim_t D(q_t, \tilde{q}_t) = \mathbb{E}[|f_t(s)|] m.$$

(28)

V. CONCLUSION

For $m$ dimensional plants, we have proven the existence of a time-invariant data compression architecture and controller that can achieve any feasible LQG control performance given a feedback bitrate within approximately $2 + 1.26 m$ bits of a known lower bound. Using the “Shannon-type” source codes described in [6, Section IV.A], it can be shown that this overhead can be reduced to $1 + 1.26 m$ bits. The difference between the lower bound and the rate achieved by the dither free, but time-varying, achievable architecture in [5] is logarithmic in the plant dimension (i.e. $O(\log(m))$). This follows from the use of more sophisticated lattice quantizers [5]. An opportunity for future work is to demonstrate TI achievability without the use of dithering and with more sophisticated quantization.

While we have proved that the minimum bitrate can nearly be achieved with a time-invariant source codec, there still remains the problem of developing a practical implementation of this source coding scheme. Numerical experiments would lend credence to these theoretical results. While the time-varying achievability approaches in [4] [5] require the precise construction of codebooks in accordance with the PMF of the quantizer output, the long-term analyses of Section IV could be useful in proving bounds on the performance of adaptive compression schemes based on, for example, [20].
