ABSTRACT

Recently Tsuji & Nakajima and Tsuji et al. have developed a method of molecular line spectroscopy of M dwarfs with which carbon and oxygen abundances are derived respectively from CO and H2O lines in the K band. They applied this method to Gliese 229A (Gl 229A), the primary star of the brown dwarf companion, Gliese 229B (Gl 229B). The derived abundances of Gl 229A are log AC = −3.27 ± 0.07 and log AO = −3.10 ± 0.02, which are close to the classical values of the solar abundances of carbon and oxygen. We generate model spectra of Gl 229B for the metallicity of Gl 229A as well as for the classical solar metallicity (log AC = −3.40 and log AO = −3.08). We find that the differences in the resulting spectra are not so large for differences in metallicity of 0.1 dex or so, but we now discuss the spectrum of Gl 229B on the basis of reliable metallicity. From the literature, the lower limit to the age of Gl 229A is found to be 0.3 Gyr. From the kinematics of Gl 229A, we evaluate the upper limit to the age of Gl 229A to be 3.0 Gyr. The observed and model spectra are compared and the goodness of fit is obtained in the range of model parameters 750 ≤ T eff ≤ 1000 K and 4.5 ≤ log g ≤ 5.5. Among the candidates that satisfy the age constraint, the best combinations of model parameters are (T eff, log g) = (800 K, 4.75) and (850 K, 5.0), while acceptable combinations are (750 K, 4.75), (850 K, 4.75) and (900 K, 5.0).

Key words: brown dwarfs – stars: abundances – stars: individual (Gl 229A, Gl 229B) – stars: low-mass

1. INTRODUCTION

Since its discovery in 1995, Gliese 229B (Gl 229B), a companion to an M dwarf, has been regarded as the prototype T dwarf (Nakajima et al. 1995; Oppenheimer et al. 1995). Although many T dwarfs have been found in the field by large surveys such as SDSS (Strauss et al. 1999; York et al. 2000), 2MASS (Burgasser et al. 1999; Skrutskie et al. 2006), UKIDSS (Lawrence et al. 2007; Warren et al. 2007) and WISE (Wright et al. 2010; Mace et al. 2013), Gl 229B remains as one of the best studied T dwarfs to date. Although the overall energy distribution of Gl 229B was reproduced by early model spectra fairly well (Allard et al. 1996; Marley et al. 1996; Tsuji et al. 1996), there were discrepancies in detail between the model and observed spectra. With these models, the effective temperature was found to be around 900 K, but surface gravity and metallicity were poorly known. Based on the progress of observations in late 1990s, attempts were made to improve the models. Saumon et al. (2000) showed that (T eff, log g, [M/H]) = (870 K, 4.5, −0.5), (940 K, 5.0, −0.2) and (1030 K, 5.5, 0.0) are all acceptable combinations of the parameters, while Leggett et al. (2002) claimed that the best fit combination of the model parameters is (T eff, log g, [M/H]) = (1000 K, 3.5, −0.5) which corresponds to an age of 30 Myr. Despite the accumulation of more observational data, the determination of stellar parameters is far from conclusive. In the mean time, more and more T dwarfs were discovered, and in 2006, a unified near-infrared spectral classification scheme for T dwarfs was presented by Burgasser et al. (2006). According to this scheme, Gl 229B was classified as a T7 peculiar object, and after this classification, Gl 229B appears to have been forgotten in the literature.

The metallicity and age of the primary star Gl 229A are expected to be the same as those of Gl 229B. The metallicity of Gl 229A is controversial and the derived values so far are [M/H] = +0.15 ± 0.15 (Mould 1978), −0.2 ± 0.4 (Schiavon et al. 1997), and −0.5 (Leggett et al. 2002). The age indicators are the kinematics of the young disk population and stellar activity as a flare star, and based on them Leggett et al. (2002) claimed that Gl 229A could be as young as 30 Myr.

In this paper, we apply newly determined carbon and oxygen abundances of Gl 229A (Tsuji & Nakajima 2014; Tsuji et al. 2015) to model the atmosphere of Gl 229B. We also reexamine the age of Gl 229A from the points of view of the kinematics and stellar activity. We then give the combinations of the good fit parameters of Gl 229B, which satisfy the age constraint.

2. CARBON AND OXYGEN ABUNDANCES OF GL 229A

The details of the determination of carbon and oxygen abundances of M dwarfs including Gl 229A are described elsewhere (Tsuji & Nakajima 2014; Tsuji et al. 2015) and a brief summary is given here.

The K-band echelle spectrum of Gl 229A with a resolution of 20,000 was obtained at the Subaru Telescope, using IRCS (Kobayashi et al. 2000) with the natural guide star adaptive optics. Before the spectral line analysis, Tsuji & Nakajima (2014) calculated the effective temperature and the surface gravity. The effective temperature T eff = 3710 K was estimated from the newly derived log T eff − M 3.4 relation, where M 3.4 is the absolute magnitude at 3.4 μm based on the WISE W1-band flux and the Hipparcos parallax. The surface gravity was estimated to be log g = 4.77 using the temperature–radius relation and mass–radius relation derived by Boyajian et al. (2012).

The new analysis of spectral lines is based on the fact that pseudo-continua are seen both on the observed and model spectra. The observed spectrum of Gl 229A is depressed by numerous weak lines of H2O, by which a pseudo-continuum is created. On the other hand, both the true- and pseudo-continua are evaluated on the model spectrum. The pseudo-continuum on the model spectrum is generated using the recent
Almost all the carbon atoms are in the form of CO molecules in the M dwarf atmosphere of Gl 229A. This situation is not changed by the changes of physical condition in the photosphere, and this is the reason that the numerous CO lines are excellent abundance indicators of carbon. H2O molecules consume a large portion of oxygen left after the CO formation and they are stable in the photosphere of Gl 229A. Similarly to the determination of carbon abundance from CO lines, oxygen abundance is determined from the analysis of H2O lines.

The resultant carbon and oxygen abundances are log \( A_C = -3.27 \pm 0.07 \) and log \( A_O = -3.10 \pm 0.02 \) respectively. The carbon abundance is higher than the classical high solar abundance of log \( A_C = -3.40 \), while the oxygen abundance is slightly lower than the classical high solar abundance of log \( A_O = -3.08 \), and the C/O ratio of 0.68 ± 0.12 is slightly higher than the solar value of 0.48 (Grevesse et al. 1991).

### 3. BROWN DWARF MODELS OF GL 229B

We compare the observed spectrum of Gl 229B between 0.8 and 5.1 \( \mu \)m obtained from the archive by Leggett (http://staff.gemini.edu/~sleggett/LTdata.html) with a set of model spectra based on the carbon and oxygen abundances of Gl 229A. The Gl 229B spectrum in the archive is a composite of several spectra with flux calibrations based on photometry: Schultz et al. (1998) Hubble Space Telescope (HST)/STIS spectrum, retained their calibration, attached at 1.023 \( \mu \)m to the Geballe et al. (1996) \( HJ \)K spectrum flux calibrated as per Leggett et al. (1999) plus the far-red spectrum fluxed by Golimowski et al. (1998) (HST) 0.81 \( \mu \)m and 1.04 \( \mu \)m photometry, which includes the Oppenheimer et al. (1998) L band spectrum recalibrated to 2.98–4.15 \( \mu \)m and the Noll et al. (1997) 5 \( \mu \)m spectrum calibrated with UKIRT photometry from Golimowski et al. (2004).

To compare with the observed spectrum, we first use the model spectra in a dust free subset based on the classical C and O abundances (Ca-series based on case \( a \) abundance) from the database of the Unified Cloudy Models (http://www.mtk.ioa.s.u-tokyo.ac.jp/~tsuji/export/ucm2) (Tsuji 2002, 2005). Also we newly prepare a small grid of model photospheres (without dust clouds) for the metallicity scaled to the carbon abundance of Gl 229A, i.e., all the metals are increased except for He, Li and O by \(-3.27 - (-3.40) = +0.13 \) dex against the classical solar abundances referred to as case \( a \). The oxygen abundance is kept at \(-3.10 \), the value for Gl 229A. We use these abundances to generate model spectra of \( R = 600 \) (about the same as the resolution of the observed spectrum). In the brown dwarf that is as cool as Gl 229B, the dust layer lies deep in the atmosphere and there is not a significant effect on the photospheric emission (Tsuji 2002). Therefore the use of dust-free models is justified.

Before the comparison of the observed and model spectra, we first investigate the significance of the effect of the non-solar metallicity of Gl 229A on Gl 229B’s spectrum by comparing the classical solar metallicity model (i.e., of log \( A_C = -3.40 \) and log \( A_O = -3.08 \)) with the model with the metallicity of Gl 229A for \( T_{\text{eff}} = 900 \) K and log \( g = 5.0 \). Inspection of Figure 1 reveals that CH\(_4\) bands (at 1.6, 2.3, and 3.5 \( \mu \)m) are slightly stronger while H\(_2\)O bands (at 1.4, 1.8 and 2.7 \( \mu \)m) are slightly weaker in the model based on the metallicity of Gl 229A, as expected for the increased carbon and decreased oxygen. The differences in the spectra, however, are not very large at a resolution as low as 600. The oxygen abundance of Gl 229B is not much different from the classical solar abundance, and this is an advantage, since the evolutionary models we use to interpret the spectra (Burrows et al. 2001) are calculated only for the solar metallicity.

The limitations of the model and observed spectra should also be noted before their comparison. The \( H\)-band methane absorption in the model spectra is calculated by a band model and the agreement with the observed spectrum at this portion of the spectrum is not so good. The \( K\)-band methane absorption in the model spectra is calculated by a line list. However the quality of the line list is not so great and the agreement of the model and observed spectra at this portion (2.2–2.4 \( \mu \)m) is not so good either. The model spectra are based on equilibrium chemistry and a feature related to disequilibrium chemistry, the 4.6 \( \mu \)m CO fundamental band (Noll et al. 1997), is not reproduced. On the other hand, the CO absorption feature in the observed spectrum is very noisy and it cannot be analyzed simultaneously with other features. Signal-to-noise ratios at individual data points of the observed spectrum are unknown and the \( \chi^2 \) test based on the absolute value of \( \chi^2 \) is not possible.

Because of the limitations mentioned above, we focus our attention to good portions of the observed and model spectra, namely, wavelength segments at (1.0–1.35 \( \mu \)m), (1.45–1.6), (1.8–2.2) and the red wing of the \( L\)-band methane feature.
(3.6–4.0μm) for which a line list (R. Freedman 2005, private communication) is available for modeling. Since we do not know the signal-to-noise ratio of each data point, as a proxy for a χ², we define a relative reduced χ², χ²_r, by assigning a constant signal-to-noise ratio, C = 1, as

\[ \chi^2_r = \frac{1}{N-1} \sum \left( \frac{C}{f_j} \right)^2 \left( \frac{f_j \text{(obs)}}{f_j \text{(model)}} - 1 \right)^2, \]

(1)

where j indicates the jth data point and N is the number of data points. Since \( C = f_j \text{(obs)}/\sigma_j, C f_j \text{(obs)} = 1/\sigma_j \), where \( \sigma_j \) is the standard deviation, which is unknown like C. There is no significance in the value of C. Since we are dealing with only one object, Gl 229B, the usefulness of the relative reduced χ²_r is justified. There are 1416 data points in all and the fitting parameter is the radius of the model brown dwarf.

A wide range of parameter space is explored in the model fitting. We calculate 30 model spectra with \( T_{\text{eff}} = 750, 800, 850, 900, 950 \) and 1000 K and with log \( g = 4.5, 4.75, 5.0, 5.25 \) and 5.5. The results of the model parameters and goodness of fit (GOF), \( \chi^2_r \), are given in Table 1. From the radius obtained by the fitting and log \( g \) of a model brown dwarf, its mass is derived.

The bolometric luminosity of Gl 229B has three determinations. Combining spectroscopic and photometric data from 0.82 to 10 μm, Matthews et al. (1996) found \( L = 6.4 \times 10^{-6} L_\odot \). With their own \( JHKL' \) photometry, Leggett et al. (1999) obtained \( L = 6.6 \pm 0.6 \times 10^{-6} L_\odot \). From a recalibration using the \( HST \) photometry of Golimowski et al. (1998), Saumon et al. (2000) found \( L = 6.2 \pm 0.55 \times 10^{-6} L_\odot \). We here adopt the middle value of the bolometric luminosity \( L = 6.4 \times 10^{-6} L_\odot \) and the evolutionary models by Burrows et al. (2001) to estimate the ages of the model brown dwarfs, which are given in column 5 of Table 1.

4. AGE OF GL 229A

4.1. Kinematics of Gl 229A

The space velocity of Gl 229A is \( (U_\odot, V_\odot, W_\odot) = (+12, -11, -12) \) in units of km s⁻¹. The solar motion in the Local Standard of Rest (LSR) frame of reference is \( (U, V, W) = (10.0, 5.2, 7.2) \) (Dehnen & Binney 1998) and the velocity of Gl 229A in the LSR frame is \( v(LSR) = 25.5 \) km s⁻¹, which is significantly smaller than the LSR velocity of the average disk population of \( v = 43 \) km s⁻¹ (Gilmore & Zeilik 2000). Leggett (1992) classified this star as
a young-disk star, which is reasonable from the value of the LSR velocity.

A quantitative estimate of the age is possible if we assume that the present LSR velocity of Gl 229A is produced by a stochastic process in the galactic disk. The total velocity dispersion \( \sigma_t \) (\( \text{km} \text{s}^{-1} \)) in the LSR frame, as a function of stellar age \( \tau \) (Gyr), is described by

\[
\sigma_t(\tau)^3 = 1000 + 8.19 \times 10^4 \left[ \exp\left(\frac{\tau}{T}\right) - 1 \right],
\]

where \( T = 5 \) Gyr (Gilmore & Zeilik 2000).

The fraction of stars with random velocities smaller than \( v(\text{LSR}) \) for a given velocity dispersion \( \sigma_t \), \( F(\sigma) \), is given by the isotropic Boltzmann distribution,

\[
F(\sigma) = \int_0^{v(\text{LSR})} \sqrt{\frac{2}{\pi \sigma^3}} \exp\left(-\frac{v^2}{2\sigma^2}\right) v^2 dv.
\]

The values of \( F(\sigma) \) are given for \( \tau \) and \( \sigma \) in Table 2. According to the table, the probability that Gl 229A is actually younger than 3.0 Gyr is just greater than 94%. We adopt 3.0 Gyr as the upper limit to the age of Gl 229A.

### 4.2. Stellar Activity of Gl 229A

While Gl 229A is shown to be a young-disk star, the time-integrated energy in the flare light is much lower than for "normally active" flare stars. M dwarfs with high chromospheric activity show Balmer lines in emission, while Gl 229A shows Balmer lines in absorption indicating a low level of chromospheric activity (Byrne et al. 1985). The stellar activity indicates that Gl 229A is not extremely young, but not so old. As a quantitative analysis, Gizis et al. (2002) obtained a lower limit to the age of Gl 229A based on the absence of H\(\alpha\) emission and their argument is summarized in the following.

The analysis of M dwarfs in open clusters by Hawley et al. (1999) suggests an approach to an age-activity relation. While the activity levels of stars in a given cluster exhibit considerable scatter, there is a well-defined \( V - I_c \) color at which activity becomes ubiquitous. All stars redder than this color are dMe (defined as EW(H\(\alpha\)) > 1.0 \(\AA\)), while the bluer stars are dM without emission. Observations exist for M dwarfs in six clusters: IC 2602 and IC 2391 (30 Myr), NGC 2516 and Pleiades (125 Myr), Hyades (625 Myr), and M67 (4.0 Gyr). Hawley et al. (2000) have used these observations to determine the relationship between the "H\(\alpha\) limit" color and the age,

\[
V - I_c = 2.54 + 1.05 \log \tau,
\]

where \( \tau \) is the age in Gyr. For Gl 229A, Gizis et al. (2002) used H\(\alpha\) absorption and \( V - I = 2.01 \) to derive the lower limit to the age, 0.32 Gyr. Based on this age limit, Gizis et al. rule out the young age of 30 Myr advocated by Leggett et al. (2002) and suggest that the synthetic spectra from model atmospheres are not yet adequate for age determinations. We adopt 0.3 Gyr as the lower limit to the age of Gl 229A, taking into account the error in the use of \( V - I \) instead of \( V - I_c \).

### 5. Interpretation of Models of Gl 229B

From the previous section, we have given the range of the age of Gl 229A to be between 0.3 and 3.0 Gyr. In column 7 of Table 1, whether a model satisfies this age constraint or not is given by Y or N. The highest gravity models for log \( g = 5.5 \) are all ruled out, because the model brown dwarfs for \( T_{\text{eff}} \leq 900 \) K are more massive than the hydrogen burning limit and the model brown dwarfs for \( T_{\text{eff}} = 950 \) and 1000 K are older than 3 Gyr. The relative reduced \( \chi^2 \), \( \chi^2_r \), is given in column 6 and the ranking of the GOF is given by \( A(\chi^2_r < 0.070) \), \( B(0.070 \leq \chi^2_r < 0.075) \), and \( C(0.075 \leq \chi^2_r) \) in column 8.

There are two models which satisfy the age constraint (Y), and GOF = A, whose physical parameters are \( T_{\text{eff}} = 950 \) and 1000 K. The relative reduced \( \chi^2 \), \( \chi^2_r \), is given in column 6 and the ranking of the GOF is given by \( \chi^2_r < 0.070 \), \( B(0.070 \leq \chi^2_r < 0.075) \), and \( C(0.075 \leq \chi^2_r) \) in column 8.

There are two models which satisfy the age constraint (Y), and GOF = A, whose physical parameters are \( T_{\text{eff}} = 950 \) and 1000 K. The relative reduced \( \chi^2 \), \( \chi^2_r \), is given in column 6 and the ranking of the GOF is given by \( \chi^2_r < 0.070 \), \( B(0.070 \leq \chi^2_r < 0.075) \), and \( C(0.075 \leq \chi^2_r) \) in column 8.

There are three models with (age constraint, GOF) = (Y, B). Their physical parameters are \( T_{\text{eff}} = 950 \) and 1000 K. The relative reduced \( \chi^2 \), \( \chi^2_r \), is given in column 6 and the ranking of the GOF is given by \( \chi^2_r < 0.070 \), \( B(0.070 \leq \chi^2_r < 0.075) \), and \( C(0.075 \leq \chi^2_r) \) in column 8.

There are three models with (age constraint, GOF) = (Y, B). Their physical parameters are \( T_{\text{eff}} = 950 \) and 1000 K. The relative reduced \( \chi^2 \), \( \chi^2_r \), is given in column 6 and the ranking of the GOF is given by \( \chi^2_r < 0.070 \), \( B(0.070 \leq \chi^2_r < 0.075) \), and \( C(0.075 \leq \chi^2_r) \) in column 8.

### Table 2

Age, Velocity Dispersion and Fraction of Stars with \( v < v(\text{LSR}) \)

| \( \tau \) (Gyr) | \( \sigma \) (km s\(^{-1}\)) | \( F(\sigma) \) |
|----------------|-----------------|-------------|
| 0.5            | 21              | 0.312       |
| 1.0            | 27              | 0.172       |
| 1.5            | 31              | 0.121       |
| 2.0            | 35              | 0.088       |
| 3.0            | 41              | 0.057       |
| Average disk   | 43              | 0.050       |

Note. \( F(\sigma) \) is the fraction of stars whose velocities generated by a stochastic process are smaller than \( v(\text{LSR}) \). The probability that a star is younger than the age \( \tau \) is given by \( 1 - F(\sigma) \).

### Figure 2

Observed spectrum (red line) of Gl 229B and a model spectrum for the metallicity of Gl 229A (green line). Model parameters are \((T_{\text{eff}}, \log g, m, \tau) = (800 K, 4.75, 0.028 M_{\odot}, 1.1 \text{ Gyr})\). This is one of the two models with the ranking of goodness of fit GOF = A that satisfies the age constraint. There are two gaps in the observed spectrum between 2.59 and 2.99 \(\mu m\) and between 4.15 and 4.51 \(\mu m\).
As an example of the poor fit models, the spectrum for the parameters, (1000 K, 5.0, 0.016 M⊙, 0.48 Gyr), is plotted in Figure 4.

To summarize, we consider that the spectra for (Y, A) models are the best fits and those for (Y, B) models are reasonable fits to the observed spectrum. In terms of the effective temperature and surface gravity, \( T_\text{eff}, \log g \) = (800 K, 4.75) and (850 K, 5.0) are the best fit parameters, while (750 K, 4.75), (850 K, 4.75) and (900 K, 5.0) are still acceptable model parameters.

### 6. COMPARISON WITH OTHER WORKS

#### 6.1. Metallicity of Gl 229A

As far as we are aware, there have been three determinations of the metallicity of Gl 229A. Mould (1978) obtained high resolution spectra in the \( H \) and \( K \) band using the Fourier Transform Spectrometer at KPNO with a resolution \( R \approx 20,000 \). He analyzed Al, Ca, and Mg lines and found \( \text{[M/H]} = +0.15 \pm 0.15 \). The effective temperature and the surface gravity he adopted are \( T_\text{eff} = 3614 \text{ K} \) and \( \log g = 4.75 \) respectively, which are in good agreement with the estimates \( T_\text{eff} = 3710 \text{ K} \) and \( \log g = 4.77 \) by Tsuji & Nakajima (2014).

Schiavon et al. (1997) obtained \( \text{[Fe/H]} = -0.2 \pm 0.4 \) through analysis of the FeH Wing-Ford band at around 1 \( \mu \text{m} \) from a medium resolution spectrum of \( R \approx 12,500 \). The effective temperature of their best fit model of \( T_\text{eff} = 3300 \text{ K} \) is significantly lower than the estimate by Tsuji & Nakajima (2014). The two determinations of the metallicity (Mould 1978; Schiavon et al. 1997) are both consistent with solar metallicity (within the error bars).

Leggett et al. (2002) fit with model atmospheres a spectrum covering from 0.8 to 2.5 \( \mu \text{m} \) with a resolution \( R \approx 800 \) and a spectrum covering from 1.12 to 1.22 \( \mu \text{m} \) with a resolution \( R \approx 5,800 \). Best fit model parameters are \( T_\text{eff}, \log g, \text{[M/H]} \) = (3700 K, 4.0, −0.5) and (3700 K, 3.5, −0.7). Although the effective temperature is in good agreement with our estimate, \( \log g \) and \( \text{[M/H]} \) are significantly lower than our values \( \log g = 4.77 \) and \( \text{[C/H]} = +0.13 \pm 0.07 \). The metallicity obtained by Leggett et al. (2002) is definitely lower than solar metallicity. The application of evolutionary models implies that the age of Gl 229A is as young as 30 Myr. As mentioned in Section 4.2, Gizis et al. (2002) rule out this young age and suggest that the problem is in the model spectra by Allard et al. (2001) used by Leggett et al. (2002).

### 6.2. Metallicity of Gl 229B

Saumon et al. (2000) do not use any information about Gl 229A and their abundance analysis is based on the bolometric luminosity \( L \) of Gl 229B alone. Since \( L \) is known, a determination of the surface gravity \( g \) fixes \( T_\text{eff} \), the radius, the mass, and the age of Gl 229B, as well as the metallicity. It is assumed that evolutionary models for solar metallicity (Burrows et al. 1997) are applicable for non-solar metallicity. They fit the observed and model spectra by eye. They analyze the "red" spectrum from 0.83 to 1 \( \mu \text{m} \) \((R \approx 2250), J(R \approx 2400), H(R \approx 2100), \) and \( K(R \approx 2800) \) spectra separately, and derive the \( \text{H}_2\text{O} \) abundances, or \( \text{[O/H]} \)’s. They interpret \( \text{[O/H]} \) as the metallicity \( \text{[M/H]} \). No overall fitting from 0.8 to 5 \( \mu \text{m} \) is done. For a given \( \log g \), the optimal \( \text{[M/H]} \) was obtained out of a set of four \( \text{[M/H]} \)’s for different wavelength bands. For three values of \( \log g \), they generated three models \( (ABC) \) with optimal parameters: \( (T_\text{eff}, \log g, \text{[M/H]} ) = A(870 \text{K}, 4.5, −0.5), B(940 \text{K}, 5.0, −0.3) \) and \( C(1030 \text{K}, 5.5, −0.1) \). They quote the error in abundance to be \( ±0.1 \). In terms of the metallicity the model \( C \) is the closest to our models, but \( \log g \) is out of the range. The compromise is the model \( B \) for which the counterpart of our model is \( ( T_\text{eff}, \log g, \text{[M/H]} ) = (900 \text{K}, 5.0, +0.13) \).

Leggett et al. (2002) use the 0.84–4.15 \( \mu \text{m} \) spectrum for Gl 229B taken from Leggett et al. (1999) and also use the 4.5–5.1 \( \mu \text{m} \) spectrum from Noll et al. (1997) to fit the model spectra by eye. The best fit model parameters are \( ( T_\text{eff}, \log g, \text{[M/H]} ) = (1000 \text{K}, 3.5, −0.5) \). Although the metallicity \( \text{[M/H]} = −0.5 \) is in agreement with the value obtained by Saumon et al. (2000), the surface gravity \( \log g = 3.5 \) is extremely small. The inspection of the best fit model spectra in comparison with the observed spectrum reveals significant discrepancies in the \( Z, H, \) and \( K \) bands. These discrepancies are much greater than those seen in our fitting of \( ZHK \) bands. The \( \text{H}_2\text{O} \) line list used by Allard et al. (2001) is of Partridge & Schwenke (1997),
while that by us is of the BT2-HITEMP2010 database (Barber et al. 2006; Rothman et al. 2010). However, the effect of line lists may be minor at low resolution. Higher resolution spectra at J, H, and K bands (Saumon et al. 2000) are also fitted by Leggett et al. (2002) with the best fit model spectra obtained from the analysis at the lower resolution. Although the H2O line list used by Saumon et al. (2000) was the same as that by Allard et al. (2001), the fit by Saumon et al. (2000) is significantly better especially at H and K bands. We suspect that the log g = 3.5 adopted by Leggett et al. (2002) is not adequate and consider that the range of log g = 5.0 ± 0.5 adopted by Saumon et al. (2000) is more appropriate.

7. DISEQUILIBRIUM CHEMISTRY

Our analysis is based on equilibrium chemistry and we do not analyze the 4.6 μm CO fundamental band. However, the effects of disequilibrium chemistry can be important for T dwarfs (Noll et al. 1997; Oppenheimer et al. 1998; Griffith & Yelle 1999; Saumon et al. 2000; Visscher & Moses 2011; Zahne & Marley 2014) and we briefly mention here the effect of the Gl 229B metallicity on the CO abundance estimation. In general, higher gravities, cooler temperatures and lower metallicity favor CH4 versus CO. Some workers estimate CO abundances, assuming low metallicity ([M/H] ≤ −0.3) (Noll et al. 1997; Visscher & Moses 2011), while others give CO abundances for low ([M/H] ≤ −0.5) and solar metallicity (Griffith & Yelle 1999; Saumon et al. 2000). Since the carbon abundance we adopt is [C/H] = +0.13 (Tsuji & Nakajima 2014), CO abundances derived for solar metallicity are of our interest. Griffith & Yelle (1999) estimate log XCO ≥ −4 for [M/H] = 0.0, while Saumon et al. (2000) give log XCO = −3.5 for [M/H] = −0.1. These values are significantly higher than for example −4.3 ≤ log XCO ≤ −3.7 obtained by Noll et al. (1997).

8. CONCLUDING REMARK

It has been two decades since the discovery of Gl 229B as the first genuine brown dwarf in 1995. It has been the only known T dwarf before a small number of field T dwarfs were discovered in 1999. As the prototype T dwarf, Gl 229B was studied intensively until early this century and efforts were made to determine its physical properties. There are two approaches in the determination of physical properties; one is to derive Teff, log g and [M/H] all from the model fitting of the Gl 229B spectrum itself and the other is to derive Teff and log g from the model fitting of the Gl 229B spectrum, but use [M/H] obtained from the spectrum of the primary star, Gl 229A. Although the latter approach is favorable because of the fewer parameters in the model fitting of the Gl 229B spectrum, it was deemed difficult because Gl 229A is an M dwarf. It was not until recently that the metallicity (abundances of C and O) was determined reliably. We used these newly determined C and O abundances of Gl 229A in the model fitting of the Gl 229B spectrum. In addition to the metallicity, the ages of the binary components are safely assumed to be the same. We estimated the range of the age of Gl 229A based on its activity and kinematics. This age constraint narrowed the combinations of physical parameters of acceptable models using the evolutionary models of brown dwarfs. It took 20 years to settle the question of physical properties of Gl 229B, although early guesses assuming the solar metallicity were not so bad.

We thank T. Geballe and S. Leggett for providing us with the Gl 229B spectrum. We also thank the anonymous referee for helpful comments which significantly improved the manuscript.
