INTRODUCTION

Self-Contained Underwater Breathing Apparatus (SCUBA) diving is a popular sport. However, improper diving may injure different organs. The majority of dive-related disorders concern otorhinolaryngology, and may include hearing loss, tinnitus, aural fullness, disequilibrium, and vertigo. Three main inner ear pathological conditions can occur underwater: inner ear barotrauma (IEB), inner ear decompression sickness (IEDS), and alternobaric vertigo (AV). IEB results from inappropriate equalization of middle ear pressure and consequent inner ear injury produced by pressure changes within the middle ear; IEDS is characterized by the formation of gas bubbles within the vessels of the inner ear during rapid ascent; AV typically develops while ascending or performing the Valsalva maneuver and can follow asymmetrical equalization of middle ear pressure transmitted via the oval and round window membranes. The clinical pictures of these pathological conditions are partly superimposable, even if they have specific peculiarities. Before starting SCUBA diving, a fit-to-dive assessment is recommended. It should include an otorhinolaryngologic examination with audiological assessment to evaluate nasal, middle ear, and tubal patency and to minimize the risk of IEB, IEDS, and AV. It is of utmost importance to identify individual risk factors and predisposing pathological conditions that favor inner ear injury before diving, to prevent acute events and preserve auditory and vestibular functions in SCUBA divers. This review aims to provide an overview of the pathological conditions characterized by inner ear injury in SCUBA divers, discussing their pathogenetic mechanisms, diagnostic work-up, and prevention.

KEYWORDS: Dizziness, vertigo, SCUBA diver

There are millions of Self-Contained Underwater Breathing Apparatus (SCUBA) divers in the world, a popular activity appreciated at any age but not free from risks.1,2 Nearly 80% of diving-related problems concern otorhinolaryngology, and the ear is the most frequently involved organ.3,4 Among ear injuries, middle ear barotrauma is the most common condition,3,4 fortunately, in most cases, it resolves spontaneously in a short time without serious complications.3 Inner ear involvement is less common but usually more serious, often resulting in permanent hearing loss, tinnitus, vertigo, and unsteadiness.5

Inner ear disorders in SCUBA divers depend on 4 gas laws: Boyle’s law (Figure 1), Henry’s law (Figure 2), Charles’s law, and Dalton’s law.1 Boyle’s law states that at a constant temperature, there is an inverse relationship between the volume of a gas and its pressure. Henry’s law states that the amount of dissolved gas in a liquid is proportional to its partial pressure above the liquid at a constant temperature. Charles’s law states that a volume of gas equals a constant value multiplied by its temperature as measured on the Kelvin scale. Dalton’s law states that the total pressure exerted is equal to the sum of the partial pressures of the individual gases.1

There are 3 pathological conditions governed by gas laws that can affect the inner ear in SCUBA divers: Inner Ear Barotrauma (IEB), Inner Ear Decompression Sickness (IEDS), and Alternobaric Vertigo (AV). This review aims to provide a comprehensive overview of the different pathological conditions characterized by inner ear injury in SCUBA divers, discussing their pathogenetic mechanisms, diagnostic work-up, and prevention.
Clinical and Research Consequences

Inner Ear Barotrauma (IEB)

IEB results from inappropriate equalization of middle ear pressure and consequent injury produced by pressure changes within the middle ear transmitted to the cochlea through the round and/or oval window. The round window is most commonly affected because it is covered by a thin membrane, whereas the oval window maintains greater stability thanks to the stapes footplate, stapedial muscle, and associated ligaments. Two pathological conditions may favor inner ear damage during descent: one with normal Eustachian tube function, the other when the tube is obstructed (Figure 3). In the first case, vigorous Valsalva maneuver may cause an uncontrolled increase in middle ear pressure with a violent outward displacement of the stapes footplate and inward movement of the slight round window membrane. In the second case, the blocked Eustachian tube does not allow middle ear pressure equalization and consequently generates a pressure difference between the middle ear, the external ear canal, and the inner ear fluids. A forceful Valsalva at this stage can increase the cerebrospinal fluid pressure (CFP) and consequently favor round or oval window rupture.

There are some anatomic risk factors that can predispose to IEB: an enlarged cochlear aqueduct orifice that may quickly increase CFP, and a shorter cochlear aqueduct, typically among pediatric divers, inducing IEB due to pressure fluctuations within the subarachnoid space.

Clinical signs and symptoms of IEB include sudden sensorineural hearing loss (SNHL), sometimes accompanied by aural fullness, tinnitus, and hyperacusis, and vestibular symptoms such as persistent or recurrent vertigo, nystagmus, dizziness, and disequilibrium. In about 40% of the cases, SNHL is typically the only presenting complaint in isolated basilar membrane tears. In about 10% of cases, vestibular symptoms are the only sign of IEB. Otoscopic findings like congestion, retraction, hematoma, and eardrum perforation related to middle ear barotrauma are often found in patients with IEB.

Before initiation of therapy, clinicians should exclude an IEDS by investigating the dive profile and the mixture of gases used and perform an otoscopic and neurologic examination, pure-tone audiometry, a fistula test, and electronystagmography (ENG). Furthermore, patients should be positioned with the head elevated, and pressure-elevating maneuvers should be prevented. A consensus on therapy does not exist, but high doses of steroids for 15-20 days are recommended as the first line of therapy, based on expert opinion. Early surgical exploration is advised when a perilymphatic fistula is suspected.
Inner Ear Decompression Sickness (IEDS)

IEDS is a phenomenon characterized by the formation of gas bubbles within the vessels of the inner ear during rapid ascent that causes an abrupt reduction in ambient pressure. All the vestibular portion of the inner ear is the most affected because it has higher tissue volume and smaller blood supply and thus a slow washout period. All this promotes supersaturation of the vestibular apparatus and consequently vascular bubble overload. Although the exact pathogenetic mechanism is still unclear; it has been speculated that gas bubbles can interact with the endothelium of blood vessels in the labyrinth and trigger an inflammatory reaction with the activation of the coagulation cascade and subsequent hypoxic injury can occur. Another plausible hypothesis is the direct damage of membranous labyrinth and local microvessels by the formation of microbubbles in the endolymphatic and perilymphatic spaces. Yet another theory is that of arterial gas emboli traveling from venous circulation through a right-to-left cardiac shunt (RLS) and subsequent occlusion of the labyrinthine artery. RLS is often present in patent foramen ovale (PFO), is relatively common, and is seen in up to 25% of the general population and nearly 50% of SNHL cases. The risk factors are old age, female gender, alcohol consumption, overweight, and obesity.

Vestibular symptoms are more frequent than cochlear ones (such as hearing loss), occur within 2 hours after the dive, and include vertigo, dizziness, nausea, and vomiting. The diagnosis of IEDS is superimposable to IEB (Table 1). The neurological investigation should be performed, as it has prognostic value.

Treatment requires immediate supplemental oxygen and recompression.

Alternobaric Vertigo (AV)

AV is a condition characterized by transient vertigo that typically develops while ascending or performing the Valsalva maneuver. AV can follow asymmetrical equalization of middle ear pressure transmitted via the oval and round window membranes. Women are more frequently affected than males, although reasons are still unclear.

Risk factors for AV include noise exposure during diving, cold-water diving, previous barotrauma, recurrent otitis media, female gender, unilaterally blocked Eustachian tube or function, and difficulty in clearing ears during diving.

AV’s clinical features include transient vertigo that lasts from seconds to minutes, typically accompanied by nausea and sporadically by vomiting. The typical triad is transient vertigo, no auditory symptoms, and difficulty equalizing middle ear pressure.

When dizziness occurs underwater, it is appropriate to ascend slowly, using the Frenzel technique, or alternatively, the Toynbee maneuver; if unsuccessful, descend to perform the Valsalva maneuver. In fact, decreased visibility and buoyancy underwater result in impaired visual and proprioceptive cues, consequently increasing the reliance on vestibular information. Therefore, if a vestibular disorder occurs underwater, it could pose an increased risk to the diver’s safety. Divers should learn how to handle vomiting underwater before diving.

Recommendations to Reduce the Risk of Inner Ear Injury

Before starting SCUBA diving, a fit-to-dive assessment is recommended to exclude physical conditions contraindicated in this activity. Particularly, an otolaryngologic examination with audiological assessment should be performed to evaluate nasal, middle ear, and tubal patency and function to minimize the risk of IEB, IEDS, and AV. A careful inspection of the nasal cavity and of the naso-pharyngeal orifice of Eustachian tubes is highly recommended to identify causes of nasal obstruction like allergic rhinitis, deviated septum, turbinate hypertrophy, and nasal polyps. Furthermore, an otomicroscopy and pneumatic otoscopy are recommended to better visualize external the auditory canal and tympanic membrane at rest and when moving in response to pressure. Audiological assessment should include pure-tone audiometry, tympanometry, and Eustachian tube function tests. Tubal function tests can be affected by many factors and may not always show exact function. However, size of mastoid aeration can be related to the long-term ability of the Eustachian tube function. Thus, measuring the degree of mastoid pneumatization can also be used to indirectly evaluate pressure equalization potential. Moreover, in selected patients, a

Table 1. Clinical Features and Therapeutic Approach to Middle and Inner Ear Conditions Occurring During a Dive

| Involved organs | Cochlea and vestibule | Cochlea | Vestibule |
|-----------------|-----------------------|---------|----------|
| Diving stage    | During ascent or descent | During ascent | During ascent and deep diving |
| Onset of symptoms | During diving | During diving | Symptom-free interval after diving |
| Middle ear involvement | Often | Absent | Absent |
| Hearing alterations | Sensorineural or mixed hearing loss; aural fullness; tinnitus; hyperacusis | Absent | Sensorineural hearing loss; aural fullness; tinnitus |
| Vestibular alterations | Dizziness or vertigo; Nystagmus toward the healthy side; Canal paresis (caloric test); Head impulse test toward the affected side | Transient vertigo; Transient nystagmus beating toward the pressurized ear; Normal caloric and head impulse test | Dizziness or vertigo; Nystagmus toward the healthy side; Canal paresis (caloric test); Head impulse test toward the affected side |
| Therapy | High dose steroids for 15-20 days; Surgical exploration if fistula is suspected | No therapy; Toynbee maneuver during ascent; Valsalva maneuver during descent | Supplemental oxygen and recompression |
cardiovascular examination with an echocardiogram and transcranial doppler ultrasound should be performed to identify a PFO and to rule out an RLS.\textsuperscript{24,29-31}

During diving, middle ear equalization using the Valsalva, Toynbee, or Frenzel maneuvers should be performed to prevent IEB and AV. The Eustachian tube opens easier in the head- or ear-up position than in the head-down position. Therefore, divers who have difficulties opening their ears can be advised to dive feet-down.\textsuperscript{44,45}

Diving should be suspended whenever middle ear equalizations become difficult. In cases of recurrent attacks of dizziness and/or hearing alterations because of diving, an otoneurologic examination is recommended, including high-resolution computed tomography of the temporal bone to rule out anatomic risk factors such as widened cochlear aqueduct orifice and enlarged internal auditory canal.\textsuperscript{5,13,19,40}

In patients with Eustachian tube dysfunction, balloon tuboplasty may be helpful to prevent equalization problems while diving, even though there is no clear evidence of success.\textsuperscript{13,46}

Diving should be suspended whenever middle ear equalizations become difficult, especially when a diver has an upper respiratory tract infection. It should also be suspended in patients undergoing some types of surgery, such as middle ear surgery, cochlear implantation, and sinus surgery, and the return to diving should follow strict recommendations.\textsuperscript{46} Diving activity can resume 3 months after myringoplasty and tympanoplasty with or without insertion of a partial ossicular replacement prosthesis.\textsuperscript{47,49} Some surgical techniques can be preferred in divers.\textsuperscript{48} After stapes surgery, it is necessary to examine otoneurologic and tubal function before starting a diving activity, to evaluate the vestibular function and exclude a labyrinthitis.\textsuperscript{47,49,50} However, all divers who undergo ossiculoplasty or stapedectomy must be warned of potential risks.

Patients with cochlear implants should be assessed before starting or resuming diving activities because risk of inner ear injury exists.\textsuperscript{51} After sinus surgery, it is a good practice to perform a test drive under supervision before certifying fitness to dive.\textsuperscript{17}

CONCLUSION

SCUBA diving has become a progressively popular sport worldwide. Otologic disorders related to diving are common and sometimes extremely dangerous, especially when the inner ear is involved. Inner ear damage while diving constitutes a potentially life-threatening situation when occurring underwater because it may induce disorientation, anxiety, and panic. The identification of individual risk factors and predisposing pathological conditions that favor inner ear injury before diving is of utmost importance to prevent acute events and preserve auditory and vestibular functions in SCUBA divers.
