Accepted 1 December 2015

Abstract. A substantial body of research evidence is indicative of disproportionately slowed information processing speed in a wide range of multi-trial, computer-based, neuroimaging- and electroencephalography-based reaction time (RT) tests in Alzheimer’s disease and mild cognitive impairment (MCI). However, in what is arguably a dichotomy between research evidence and clinical practice, RT associated with different brain functions is rarely assessed as part of their diagnosis. Indeed, often only the time taken to perform a single, specific task, commonly the Trail making test (TMT), is measured. In clinical practice therefore, there can be a failure to assess adequately the integrity of the rapid, serial information processing and response, necessary for efficient, appropriate, and safe interaction with the environment. We examined whether a typical research-based RT task could at least match the TMT in differentiating amnestic MCI (aMCI) from cognitively healthy aging at group level. As aMCI is a heterogeneous group, typically containing only a proportion of individuals for whom aMCI represents the early stages of dementia, we examined the ability of each test to capture intra-individual variation in performance. The results indicate that as well as significant slowing in performance of the operations involved in TMT part B (but not part A), individuals with aMCI also experience significant slowing in RT compared to controls. The results also suggest that research-typical RT tests may be superior to the TMT in differentiating between cognitively healthy aging and aMCI at group level and in revealing the performance variability one would expect from an etiologically heterogeneous disorder such as aMCI.

Keywords: Dementia, information processing speed, mild cognitive impairment, reaction time

INTRODUCTION

Although information processing speed tends to slow with age [1], disproportionate slowing appears related to cognitive limitations [2–5] and a wide range of brain disorders [6], including degenerative brain changes such as Alzheimer’s disease (AD) [6–10], vascular dementia [11], vascular cognitive impairment [12, 13], cerebral small vessel disease [14], amnestic mild cognitive impairment (aMCI) and its conversion to dementia [8] and faster decline in AD progression [15, 16].

Behaviorally, as reaction time (RT) is an important factor in relation to the integrity and efficiency of brain functions such as those involved in attention, cognition, and perception, it may provide a
required by driving.

constant need for vigilance and response to change

act with their surroundings. An example being the

efficiency by which a person can successfully inter-

repeatedly to ever-changing stimuli and thus repre-

ity to respond rapidly, efficiently, appropriately, and

arguably therefore an indicator of an individual’s abil-

ability and utilization, patterns of functional decline

and function but generated additional information

the relationship between behavioral RT and some

aspects of the brain’s structural integrity. Information

processing speed as indicated by RT (i.e., the time

elapsed between the presentation of a stimulus and

the behavioral response), measured over a number of

trials of computer-based stimulus response tests, can

represent a behavioral ‘marker’ of neurophysiologi-

cal integrity. For example, disruption to white matter

and cerebral integrity and change in neurotransmit-

ers is associated with disproportionate slowing of

and raised intra-individual variability in RT [1, 8,

23–30]. Arguably therefore this link between struc-

tural and functional integrity and behavioral RT

indicates the potential for simple RT tests as valid

adjuncts to the assessment of diagnosis, status, stage,

progression, and interventional success in dementia

and related disorders [31].

Furthermore, with appropriate methodological

design, RT can be used to assess the integrity of

specific aspects of brain function including attention,

perception, visual processing, and cognition, at

various levels of processing and in response to differ-

ent processing and resource demands [8]. Indeed, the

majority of dementia-related research studies examin-

ing RT in relation to brain structure and function

(e.g., using techniques such as DTI, EEG, MRI,

fMRI) have tended to utilize multi-trial computer-

based tasks. These have not only allowed measures of

the relationship between behavioral RT and structure

and function but generated additional information

related to performance variability, fatigue, stimuli and

threshold responses, processing load, resource avail-

ability and utilization, patterns of functional decline

and integrity, and response to intervention. RT is

arguably therefore an indicator of an individual’s abil-

ity to respond rapidly, efficiently, appropriately, and

repeatedly to ever-changing stimuli and thus repre-

sents a valid, yet easily obtained, indicator of the

efficiency by which a person can successfully inter-

act with their surroundings. An example being the

constant need for vigilance and response to change

required by driving.

Clinically, despite this research evidence, information

processing speed tends not to be assessed using a

variety of function-specific, computer-based, multi-

trial RT tests. Although a variety of RT-based tests

are available and in use clinically, in some cases

information processing speed is assessed by measur-

ing the time taken to perform a given task, namely

using a stop-watch to measure the single trial per-

formance of the pen and paper Trail Making Test

(TMT) [32–38]. The TMT is a test administered in

two parts. In Trails A, individuals are required to con-

nect a series of consecutively numbered circles that

are presented in a random pattern on the paper: a

task typically described as probing functions such as

speed of processing in relation to attention, visual

scanning and search, number recognition, numeric

sequencing, and motor speed. In Trails B, individuals

are required to connect a series of numbered and let-

tered circles alternating between the two sequences;

a task typically described as probing the efficiency

of set shifting, mental flexibility, executive func-

tion, divided attention, attention switching, visual

search set shifting, simultaneous maintenance of two

sequences, working memory and cognitive flexibil-

ity; arguably a measure of information processing

speed in relation to multiple high level, non-specific

functions [33, 34, 39]. TMT performance, in both

parts A and B, is evaluated by scoring the time for

completion in seconds, using one trial only.

Although research indicates that TMT perfor-

mance, as in RT, is slower in older compared to

younger adults [33, 40], with additional slowing

related to pathological aging such as MCI, AD [41,

42], and vascular dementia [43] (but see also [10, 15,

21, 41, 44–54]), there are potential limitations associ-

ated with the clinical use of the TMT. Although Trails

B is more difficult than Trails A, involving greater

information processing load, range and depth of oper-

ations, and arguably of greatest clinical usefulness,

not all individuals can complete it [55]. Any visual

or motor impairment due to extraneous factors such

as stroke, injury, blindness, or arthritis for example,

will affect test performance. In those circumstances

the test is not administered, or it is interpreted with

cautions. Furthermore, the fact that TMT performance

is examined over one trial only precludes the complex

analysis of speed/error trade-off, the motor and non-

motor components of reaction time, thresholds for

change, the influence of environmental factors and

stimulus properties, practice or fatigue effects, the

intra-individual variability of an individual’s perfor-

mance at any one time, and the components of rapid,
successive information processing and response, possible with the use of RT tests. RT tests arguably therefore can provide more ‘data rich’ results than the TMT. Furthermore the fact that the TMT is pen and paper-based also means that it is difficult to use in its exact clinical format in conjunction with neuroimaging, EEG, and many other imaging studies relating behavioral response with underlying physiology (although see Müller et al. [36] and Hagen et al. [34]).

Arguably, in the time it takes to administer the TMT, a highly sophisticated and function-specific RT and RT variability test (and one typically used in neuroimaging studies) could be administered using the user-friendly interfaces of computers, laptops, or mobile technology devices (e.g., tablets). Potentially, the use of such technology can permit the automatic and immediate availability and electronic transfer of results for interpretation and comparison with previous results. Taking this concept one step further, mobile device technology means that clinically relevant and research-based RT testing does not have to be performed within a clinical setting and does not necessarily require someone to administer it [56].

Although a major research focus in aMCI relates to the potential for disproportionate RT slowing as a ‘marker’ of the increased risk of developing dementia, the generally ignored fact remains that irrespective of cause, substantially slowed information processing and response may have significant detrimental impact upon daily living. Arguably, in terms of ecological validity and clinical relevance, measuring processing speed with respect to TMT performance only, means that degradation in the integrity of the operations involved in rapid responses to constantly changing or repeatedly presented information is not considered when evaluating task competences and behaviors with inherent RT components. The operations involved in processing and responding to rapid and repeated stimuli in a RT test will be different to those related to the performance of the TMT, and we suggest that measuring RT may be more akin to, ecologically valid or relevant with respect to the investigation of the integrity of information processing speed related to every day tasks which typically require repeated rapid processing, decision making, and response. Taking into account all these considerations, should information about processing speed included in the clinical diagnosis and follow-up of aMCI and dementia be based solely on TMT performance?

We address this question by investigating two measures commonly used as indicators of processing speed in aMCI and AD, namely the TMT, sometimes used in clinical assessment, and the RT component of a form of visual search test commonly employed in research and specifically that is used in a series of previous studies by Tales and colleagues (e.g., [8]), in which RT to a target appearing in isolation is compared to the time taken to respond to the same target when it is surrounded by distracting information. These tasks are similar to Trails B and Trails A, in that they are generally assumed to involve complex and higher processing levels and varying loads, attention shifting, eye movements, sequencing, suppression and inhibition of irrelevant or previously attended locations and stimuli, but unlike the TMT, numerous trails are presented in quick succession (as described in the methods section to follow). We examine in the first instance whether the visual search based RT tests can at least match the ability of the TMT to differentiate aMCI from cognitively healthy aging at group level. Secondly, as aMCI is a clinically heterogeneous group typically containing a proportion of individuals for whom aMCI represents the early stages of a dementing process, a proportion for whom it remains of unknown etiology and others for whom it is a temporary condition, we examine the ability of each test to provide intra-group variation in performance. As both disproportionately slower task-completion time and RT are related to the presence of dementia, one would expect to see some performance variability within the aMCI but not the cognitively healthy control group in both tests.

Research has also indicated that in older adults both age and educational level can influence TMT performance, although outcome appears to vary with respect to TMT scoring methods, type of analysis, and the interpretation of errors [33–35, 41, 57–62]. There is some evidence also that gender can influence RT although this effect appears to be task dependent [33, 58, 63–66]. In the present study therefore, as is common practice, education, age, and gender were matched at group level to the best of our abilities. Furthermore, as earlier research on TMT has been criticized because of the lack of inclusion of a measure of IQ [41, 67], we employed the National adult reading test (NART) [68, 69] to provide an estimate of general/pre-morbid intelligence or indeed a proxy of cognitive reserve. As previous evidence highlights the potential for outcome variability between studies of processing speed in such populations [8, 70, 71],
the same individuals are included in all tests so direct comparisons of performance can be made.

**METHODS**

This study was conducted according to the principles in the Declaration of Helsinki. It was approved by Frenchay Research Ethics Committee and all participants gave written informed consent to participate. Only individuals with the capacity to consent were included. Capacity to consent was assessed by the clinician (JH) with specialist expertise in this field and consistent with the requirements of the Mental Capacity Act.

**Participants**

Community-dwelling cognitively healthy older adults and patients with aMCI\(^+\) (multi-domain amnestic MCI) were recruited via the Bristol Memory Disorders Clinic. All had normal or corrected-to-normal vision. Medication could not be controlled but none of the participants were receiving medication or intervention deemed likely to affect cognitive or reaction-time-related function and those with aMCI\(^+\) were receiving no drug treatment or intervention for this condition, none were classed as anxious or depressed. All participants performed a typical Bristol Memory Disorders clinic battery of neuropsychological tests including Mini-Mental State Examination (MMSE) [72], WAIS-III (Wechsler Adult Intelligence Scale) subtests (digit span, similarities, picture completion) [73], Hopkins Verbal Learning Test-Revised [74], CLOX (executive clock drawing task) [75], Visual Form Discrimination Task [76], NART [68], S-word fluency and animal fluency [45], Story Recall (Adult Memory Information Processing Battery) [77], Bristol Activities of Daily Living scale (BADLS) [78], and Brief Assessment Schedule, Depression Cards (BASDEC) (screen for depression) [79]. By definition, all the cognitively healthy older adults performed at age-appropriate levels on all tests (i.e., \(z\)-score above -1.5). Individuals with a diagnosis of aMCI\(^+\) had self-reported and informant corroborated change in memory and objective decline (\(z\) scores equal or less than -1.5 in memory and at least one other area of function), in the absence of dementia and intact ability to perform activities of daily living. Exclusion criteria included past history of serious head injury, evidence of physical slowing (e.g., related to Parkinson’s disease or arthritis), stroke, and other significant neurological or psychiatric condition (see Phillips et al. [8] and [80, 81]). In total, 87 individuals took part in this research, 48 older adults with mild cognitive impairment and 39 cognitively healthy older adult controls\(^1\). The demographic details are shown in Table 1.

The cognitively healthy older adult and the aMCI\(^+\) groups did not differ significantly with respect to mean Age [\(Z = -1.65, p = 0.098\)] or mean Educational level [\(Z = -0.53, p = 0.6\)], indicating that attempts at matching these demographics between groups was successful. However, the NART score (level of pre-morbid intelligence) was significantly poorer for the aMCI\(^+\) compared to the cognitively healthy older adult group [\(Z = -3.3, p = 0.001\)]. As expected, MMSE score was significantly lower for the aMCI\(^+\) compared to the cognitively healthy older adult group [\(Z = -2.98, p = 0.003\)].

**Experimental task and procedure**

In a counter balanced procedure, the TMT (both Trails A and Trails B) and the visual search task (both target alone and target plus distracter conditions) were administered to all participants by a trained psychometrist. Testing took place within the Bristol Memory Disorders Clinic.

**The pen and paper TMT**

When administering Trails A, the psychologist provided the participants with a practice sheet as a way of visually explaining the task. Once the participants completed the practice sheet, they completed the full Trails A. For this task the participants were instructed to draw one continuous line joining a series of circled numbers in ascending order on a sheet of paper as fast as they could. They were given a maximum of 2 minutes to complete this task. Similarly for Trails B, participants were given a practice sheet and when happy with the instructions were asked to complete the full Trails B. The test required them to draw one continuous line joining a series of circled numbers and letters in ascending and alphabetical order on a sheet of paper as fast as they could. A time limit of 5 minutes is stipulated for this task. Scores are based on the number of seconds until completion and the participant’s age. If errors were made on either

\(^1\)Please note that some of the participants included in this research were part of a larger cohort Phillips et al. [8] for whom both Trails A and Trails B and visual search RT1 and RT8 conditions were completed in full.
tasks participants are immediately informed and they are allowed to correct them. Errors like this were accounted for in the time to complete the task or if they failed to complete the task in the allotted time.

The computer-based Visual Search Task

The visual search task used was one employed in several previous studies by Tales and colleagues [8, 80, 81, see also 7], in which the time taken to respond to a target (namely to discriminate whether an arrow-head was pointing to the left or right) when it appeared in isolation upon the computer screen and the time taken to respond to the same target when it was surrounded by similar but irrelevant and distracting stimuli was determined. This paradigm was presented on a Toshiba Satellite-Pro lap top computer viewed at a distance of 57 cm. Superlab software (Cedrus Corporation San Pedro, CA) was used to deliver stimulus presentation and response capture. This choice RT task included a black target, either a right or left-pointing arrow head; with participants required to indicate whether the arrow-head was pointing to the left or right. The distracting stimuli consisted of seven black arrow-heads pointing either up or down. A ‘clock-face’ configuration (see Fig. 1) was used to position the target, both when it appeared alone and when surrounded by seven distracters, in a counterbalanced arrangement in order to eliminate any visual field position-related differences in processing. The target appeared eight times at each of the possible ‘clock-face’ locations giving a total of sixty-four trials. Distracters were presented for half the trials. On each trial the central fixation cross appeared on screen for 1000 ms prior to the appearance of the target and remained on screen for the duration of the trial. The stimuli remained on screen until a response was made. Participants were instructed to fixate on the center cross at the beginning of each trial and to respond as quickly but as accurately as possible as to whether the target was pointing to the right or left by pressing one of two computer keyboard keys. After instruction, all participants were asked to explain the task to the researcher in order to demonstrate that they fully understood the task and then performed approximately 10 practice trials. The ability of the participants to fixate upon the central cross was checked at the beginning of each trial by researcher observation. The researcher was also in a position to record any lack of trial response and to prompt re-engagement of the task. Participants received no performance-feedback during testing.

DATA ANALYSIS AND RESULTS

Group mean analysis for RT speed was based on the mean values (of correct trials only) for each individual within the group. The mean response times for TMT, Trails A and B, and the mean RTs (ms) for the target alone and the target plus distracter search are displayed in Table 3, together with the corresponding standard deviation and standard error of the mean. Note that in the TMT, no participants exceeded the five-minute time limit. For the visual search tasks, only correct trials were included in the statistical analysis. Accuracy was high; the mean percentage of errors overall was low for both the cognitively healthy (3.2%) and aMCI⁺ (4.6%) groups with no evidence of speed accuracy trade off effects. No participants failed to respond to a trial and none required prompting.

In response to the generally non-normal distribution of our RT data (see Table 2, Figs. 2 and 3), SPSS

| Demographic details | Education | Age | NART | MMSE |
|---------------------|-----------|-----|------|------|
| Cognitively healthy older adults (n = 39) | Mean 14.56 | 70.5 | 118.3 | 27.1 |

Fig. 2. BOX plot of Trails A and B performance based on individual response speed (seconds).

non-parametric statistical analysis was employed in line with common practice.

**Trails A & B response time analysis**

For Trails A, analysis revealed no significant difference in group-mean response time (in seconds) between cognitively healthy aging and aMCI⁺ \[Z = -1.4, p = 0.16\]. Note, however, that whereas Trails A performance was normally distributed for the cognitively healthy older adult group, this was not the case for the aMCI⁺ group. Note also that multiple correlational analysis (with Bonferroni correction) failed to reveal any correlation of response time with age, education, NART score, or MMSE score in either group [all \(p\)-values >0.05].

For Trails B, mean response time was significantly slower in aMCI⁺ compared to cognitively healthy aging \[Z = -1.96, p = 0.05; \text{effect size (r) = 0.21}\]. For both groups, performance of Trails B was not normally distributed and multiple correlational analysis (with Bonferroni correction) failed to reveal any correlation of response time with age, education, NART score, or MMSE score in the older adult group [all \(p\)-values >0.05] and education, NART score, or MMSE score in the aMCI⁺ group [\(p\)-values >0.05], although performance of Trails B in the aMCI⁺ group was significantly correlated with age \[r = 0.522, p < 0.001 \text{ which survives Bonferroni correction; } p = 0.004\].

**Visual search target alone and target plus distracter reaction time analysis**

Mean RT in response to the target alone Visual Search task was significantly slower for the aMCI⁺

| SEM                     | 2.0                            | 7.5                            | 30.2                             | 102.5                                  |

compared to the cognitively healthy older adult group \([Z = -2.8, p = 0.006; \text{effect size (r)} = 0.3]\). For both groups RT was not normally distributed and was not significantly correlated with age, education, NART or MMSE scores [all \(p\)-values >0.05].

In response to the target plus distracters Visual Search task, mean RT was significantly slower for the aMCI + compared to the cognitively healthy older adult group \([Z = -3.5, p <0.001; \text{effect size (r)} = 0.38]\).

Although performance of this task was normally distributed for the cognitively healthy older adult group this was not the case for the aMCI + group. RT was not significantly correlated with age, education, NART or MMSE scores [all \(p\)-values >0.05] in either group.

**Gender**

Males and females in the cognitively healthy older adult group did not differ significantly in mean response time for Trails A \([Z = -0.745, p = 0.45]\) or B \([Z = -1.32, p = 0.186]\), or in RT for the target alone \([Z = -0.056, p = 0.96]\) or target plus distracters Visual Search tasks \([Z = -0.787, p = 0.43]\).

In the aMCI + group, there was no gender difference in target plus distracters Visual Search task \([Z = -1.041, p = 0.298]\), Trails A \([Z = -0.433, p = 0.665]\) or B \([Z = -0.928, p = 0.353]\) performance. In response to the target alone Visual Search task, however, males were significantly faster than females \([Z = -2.073, p = 0.038, \text{effect size (r)} = 0.3]\). It is possible that this gender difference may be related to the greater educational level of males than females in this group \([Z = -3.061, p = 0.002, \text{effect size (r)} = 0.44]\), further analysis revealed, however, that RT was not correlated with educational level \([p > 0.05]\).

Note that in both groups there was no significant difference between males and females with respect to mean age, NART score, or MMSE score and no difference in educational level within the cognitively healthy older adult group [all \(p\)-values >0.05].

**DISCUSSION**

The TMT is sometimes used clinically to assess the speed of information processing in dementia, MCI, and related disorders, by measuring the time taken to complete the task of consecutively joining a series of numbers and or letters on a sheet of paper. However, in research terms, speed of information processing is generally described with respect to reaction time, i.e., the time elapsed between the relatively rapid presentation of a stimulus and the behavioral response, measured over a number of trials at relatively short intervals. Arguably, the processing involved in processing and responding to such rapid and repeated stimuli is different from that involved in performing the TMT, and we suggest that measuring RT may indeed be more akin to, ecologically valid or relevant with respect to the investigation of the integrity of information processing speed related to everyday tasks which typically require rapid processing, decision making, and response.

However, although RT tests may, in theory, represent a clinically valid replacement of the TMT, we have not been able to identify any evidence investigating both measures in clinical populations. Here, therefore, we examined the performance of the TMT (both A and B versions) and two versions of a computer based multi-trial visual search-based RT task (a target alone and a target plus distracters condition) in the same groups of cognitively healthy older adults and patients with aMCI +, in an attempt to determine whether the visual search based RT tests can at least match the ability of the TMT to differentiate aMCI + from cognitively healthy aging at group level. Secondly, as aMCI + is a clinically heterogeneous group typically containing a proportion of individuals for whom aMCI + represents the early stages of a dementing process, a proportion for whom it remains of unknown etiology and others for whom it is a tempo-
rary condition, we examined the ability of each test to provide intra-group variation in performance. As both disproportionately slower task-completion time and RT are related to the presence of dementia, one would expect to see some performance variability within the aMCI+ but not the cognitively healthy control group in both tests.

**Trails A and B performance**

Trails A performance failed to significantly differentiate aMCI+ from cognitively healthy aging at group level. Arguably this result is indicative of a lack of sensitivity of the Trails A test to the presence of MCI. Indeed the box plot (Fig. 2) reveals just how similar the results are for the patient and control groups. Furthermore, response time was normally distributed for the cognitively healthy older adult but not for the aMCI+ group (see Table 2). Given the etiological heterogeneity of aMCI+, in that at least a proportion of such individuals would be expected to be in the prodromal stages of dementia with a generally acknowledged accompanying slowing of response time, the relative lack of individual variability in response time within this group is surprising.

In contrast, Trails B performance significantly differentiated aMCI+ from cognitively healthy aging. As shown in Fig. 2, response time is clearly slowed for the aMCI+ compared to the control group and there are a number of individuals within the aMCI+ group whose performance is represented by clear outliers. This potentially represents the within-group heterogeneity one might expect from such an etiologically varied group. However, Trails B also reveals heterogeneity of performance within the cognitively healthy older adult group; indeed response time is not normally distributed in either group (see Table 2), with both characterized by some disproportionately slower reaction times and therefore some degree of performance overlap.

**Visual search reaction time performance**

The RT in response to the simple target alone visual search test was significantly slower in aMCI+ compared to cognitively healthy aging. However, as is clear from Fig. 3, RT was abnormally distributed for both groups, with a number of disproportionately slower responses, i.e., outliers characterizing both groups and thus indicative of some degree of overlap between cognitively healthy aging and aMCI+. Nevertheless, the effect size of the significant difference in performance between the two groups was greater than that for the Trails B test (effect size ‘r’ = 0.21 and 0.3), respectively.

For the target plus distracter visual search task, mean RT was significantly slower in aMCI+ compared to cognitively healthy aging. The effect size of this outcome (r = 0.38) was greater than that exhibited for the target alone search (r = 0.3) and the Trails B (r = 0.21) tasks, indicating that the target plus distracter visual search task is the one most sensitive to aMCI+. Furthermore, whereas the distribution of RT performance was normal within the cognitively healthy older adult group for the target plus distracter visual search task this was not the case for the aMCI+ group, revealing instead a number of considerably slower responses, i.e., outliers (see the Box plot in Figs. 2 and 3, and Table 2). There is, of course, once again some degree of overlap between performance in the control and the patient group and therefore not everyone with aMCI+ reveals slower mean RT compared to cognitively healthy aging. It appears rather that the aMCI+ group contains a greater proportion of individuals with disproportionately slower, responses. However, unlike Trails A, Trails B, and the simple target alone visual search RT task, the target plus distracter visual search RT task promotes outliers, i.e., disproportionately slowed responses only within the aMCI+ group. It may be the case that this RT task does not produce as many ‘false positives’ i.e., disproportionately poor performance within the control group, as does the target alone search RT task and the Trails B test. Note also that three individuals in the aMCI+ group are outliers in both the Trails B and the target plus distracter visual search RT test. This may indicate that for some people with aMCI+, both aspects of information processing speed are abnormal whereas for others only specific aspects of such processing are affected. If this is the case, changes over time in the profile of performance of an individual may be more useful than just testing one function. As suggested by Johnstone et al. [50], profile analysis is likely to assist in making differential diagnoses between cognitive disorders, and it may be the case that the identification of distinct deficit profiles of processing speed integrity and changes over time can better identify individuals’ cognitive strengths and weaknesses.

Although such disproportionate slowing within the aMCI+ group may be related to an increased risk of developing dementia (e.g., Phillips et al. [8]; Kochan
et al. [10]), or represent a decline to dementia if such tests are administered to an individual over time, lack of follow up of all the participants in this study precludes us from making such an analysis. Such heterogeneity within the aMCI+ may, however, explain, at least in part, some of the disparity in RT outcome between previous studies, as slowing may be related to specific etiologies of aMCI+, only some of which have a neurodegenerative basis. Importantly, however, that a proportion of individuals with aMCI+ have very slow RTs, much beyond those associated with cognitively healthy aging, indicates that for some individuals processing related to continuous changes in the environment and situations in everyday life that require serial, rapid, and repeated detection, processing, and response can be significantly impaired. These effects are of potential importance irrespective of whether an individual with aMCI+ has the early stages of dementia or not.

**Gender, age, education, IQ (NART), and MMSE**

A gender-related difference in performance was evident only within the aMCI+ group. RT was significantly faster for males than females for the target alone visual search group. Although there was a significantly greater educational level for males than females in this group, which may have potentially contributed to this result, there was no significant correlation between educational level in either males or females and RT and it remains to be seen why a gender-related effect should be evident in the target alone visual search task RT only. Nevertheless this pattern of results indicates that within the same research groups, processing speed outcome and its relation to gender may be influenced by the test used, although one does have to consider that it may be a spurious effect.

In previous studies, TMT outcome has reportedly varied considerably with respect to whether or not performance is correlated with age and education (e.g., [41, 57]). In the present study we found that for the cognitively healthy older adult group, although initial analysis suggested some degree of correlation between Trails A performance speed and age, this did not survive Bonferroni correction for multiple correlational analysis; and performance was not significantly correlated with age per se for the aMCI+ group. It appears that over the relatively narrow range of ages within our data set this was a weak effect and one that only appears to occur in cognitively healthy aging. It may be the case that such a relationship occurs only when a wider range of ages is included. In contrast, although performance of Trails B was not significantly correlated with age in the control group, it was significantly correlated with age (surviving Bonferroni correction) in the aMCI+ group: a finding which if further research finds to be robust, may have implications for the interpretation of results over this age range. The finding that age is not similarly correlated with performance in both cognitively healthy aging and aMCI+ also breaks an assumption necessary for covariate analysis (if parametric analysis of RT data is attempted; another reason why we used non-parametric testing for our results). In contrast to Trails A and B, RT of both versions of the visual search task was not significantly correlated with age for either the cognitively healthy older adult or the aMCI+ groups.

Performance of Trails A, B, and both versions of the visual search RT task was not significantly correlated with educational level for either the cognitively healthy older adult or the aMCI+ groups (although there was some evidence of a correlation for Trails A performance and education for the aMCI+ group it did not survive Bonferroni correction). Although the aMCI+ group had a significantly lower IQ (NART score), explained by the lower score for females compared to males in this group, performance of none of the four tasks was significantly correlated with IQ. Performance of TMT and both visual search tasks was not significantly correlated with MMSE (note however that for the aMCI+ group, Trails B was significantly correlated with MMSE score but again this did not survive Bonferroni correction).

There is therefore some room for debate about whether some relatively small effects of age and education and MMSE occur in relation to TMT and whether they differ with respect to group. However, such effects may be contingent upon the ranges of these factors within the groups (e.g., in wider or different ranges than those used in the present study) and dependent upon the numbers tested over each age range (i.e., related to the determination of normative data in which smaller numbers tend be tested for each age range and research studies in which a narrower range of measures are usually employed).

What is clear from the present study, however, is the lack of relationship between age, education, MMSE, IQ, and visual search based RT performance. This may indicate that such tests are less susceptible to, i.e., relatively independent of, the influence of age, education, and IQ upon performance [57, 82].
Potential study limitations

Unfortunately we were unable to follow up both groups in order to determine clinical outcome thus precluding analysis of whether those individuals with outlying response times and RTs in the aMCI+ group were most likely to develop dementia. Furthermore, interpretation of the results and thus their potential for impact is limited by the fact that we did not test performance repeatedly and over various time periods. Ideally we would have combined our behavioral tasks with an imaging study in order to determine the relationship between our RT and response speed results and structural and functional integrity both at group and individual level. We would have also explored the impact of methodological manipulations of RT tests such as time pressure, processing load, and various types of distraction in order to explore deficits in a wider range of information processing operations.

Furthermore, we only measured response speed and RT in aMCI+; it would have been useful to determine the sensitivity of such tests to aMCI and to subjective cognitive decline, conditions that may represent lower stages on a continuum between health and dementia. Repeating this study with a larger sample size and wider range of demographic factors would allow further investigation in to the potential relationship between processing speed and RT and factors such as age, IQ, educational level, and level of cognitive impairment. Further research would also investigate a wider range of processing speed and RT tests typically used in research and clinically and in relation to factors such as practice effects.

Nevertheless, the very fact that the search tests seem more sensitive to aMCI+ than the Trails B tests and the fact that the search tests appear less affected by demographic factors than the TMT indicates that such tests have a place in clinical assessment.

Conclusions

These results indicate that as well as potential slowing in performance of the operations involved in the TMT used in clinical assessment, individuals with aMCI+ may also experience a substantial slowing of the rapid RT responses necessary for the safe, appropriate, and efficient environmental interaction required in real life; the importance of which is great irrespective of etiology. The results also suggest that RT tests typically used in research may be superior to the TMT in their ability to significantly differenti-
cortical vascular dementia: Short fixations but long reaction
times. *Dement Geriatr Cogn Disord* **20**, 375-380.
