ABSTRACT

Context. The low mass protostar IRAS16293-2422 is a prototype Class 0 source with respect to the studies of the chemical structure during the initial phases of life of Solar type stars.

Aims. In order to derive an accurate chemical structure, a precise determination of the source physical structure is required. The scope of the present work is the derivation of the structure of IRAS16293-2422.

Methods. We have re-analyzed all available continuum data (single dish and interferometric, from millimeter to MIR) to derive accurate density and dust temperature profiles. Using ISO observations of water, we have also reconstructed the gas temperature profile.

Results. Our analysis shows that the envelope surrounding IRAS16293-2422 is well described by the Shu “inside-out” collapsing envelope model or a single power-law density profile with index equal to 1.8. In contrast to some previous studies, our analysis does not show evidence of a large (≥ 800 AU in diameter) cavity.

Conclusions. Although IRAS16293-2422 is a multiple system composed by two or three objects, our reconstruction will be useful to derive the chemical structure of the large cold envelope surrounding these objects and the warm component, treated here as a single source, from single-dish observations of molecular emission.

1. Introduction

Understanding how our Sun and Solar System formed is arguably one of the major goals of modern astrophysics. Many different approaches contribute to our understanding of the past history of the Solar System. Analyzing the relics of the ancient eons, comets and meteorites, is one. Studying present day objects similar to what the Sun progenitor is another. Here we pursue the latter approach and analyze in detail the case of one of the best studied solar type protostars, IRAS16293-2422 (hereinafter IRAS16293). IRAS16293 is a Class 0 protostar in the ρ Ophiuchus complex at 120 pc from the Sun (Loinard et al. 2008) and has played the role of a prototypical solar-type protostar for astrochemical studies, just as Orion KL has done for high-mass protostars. This is because of its proximity and the resulting line strength of molecular emission (e.g. Walker et al. 1986; Mundt et al. 1993; Blake et al. 1994; van Dishoeck et al. 1997) to mention just a few representative works from the previous decades). It is in this source that the phenomenon of the “super-deuteration” has been first discovered, with the detection of surprising abundant multiply deuterated molecules: formaldehyde, hydrogen sulfide, methanol and water (Ceccarelli et al. 1998; Vastel et al. 2003; Parise et al. 2003; Bouter et al. 2007). It is also in this source that the first hot corino (Bottinelli et al. 2004; Ceccarelli et al. 2007) has been discovered, with the detection of several abundant complex organic molecules in the region where the dust grain mantles sublimate (Ceccarelli et al. 2000b; Cazaux et al. 2003; Bottinelli et al. 2004).

Not surprisingly, therefore, IRAS16293 has been the target of several studies to reconstruct its physical structure, namely the dust and gas density and temperature profiles (Ceccarelli et al. 2000a; Schöier et al. 2002, 2004; Jørgensen et al. 2005), the mandatory first step to correctly evaluate the abundance of molecular species across the envelope (Ceccarelli et al. 2000a) used water and oxygen lines observations obtained with the Infrared Space Observatory (ISO) to derive the gas and dust density and temperature profile. Conversely, Schöier et al. (2002) used the dust continuum observations to derive the structure of the envelope. Furthermore, while Ceccarelli et al. assumed the semi-analytical solution by Shu & co-workers (Shu 1977; Adams & Shu 1986) to fit the observational data, Schöier et al. (2002) assumed a single power law for the density distribution, and a posteriori verified that the Shu’s solution also reproduced the observational data. The two methods lead to similar general conclusions: a) the envelope of IRAS16293 is centrally peaked and with a density distribution in overall agreement with the inside-out collapse picture (Shu 1977); b) there is a region, about 300 AU in diameter, where the dust mantles sublimate (giving
rise to the phenomenon of the hot corino, mentioned above). However, the two different methods, not surprisingly, also lead to some notable differences. For example, the gas density differs by about a factor 3 in the region where the ice sublimation is predicted to occur, which leads to differences in the derived abundances of several molecular species.

Subsequent studies have built on the early ones to improve the derivation of the physical structure of IRAS16293. First, the study by Schöier et al. (2004), based on interferometric OVRO observations, concluded that the envelope has a large central cavity, about 800 AU in diameter. Then, the work by Jørgensen et al. (2005), using new SPITZER data, concluded that the envelope has an even larger central cavity, about 1200 AU in diameter. Such a large central cavity has a great impact on the whole interpretation of the hot corino of IRAS16293, as it predicts the absence of the mantle sublimation region. If the predicted cavity is real, the observed complex organic molecules must have another origin than grain mantle sublimation from thermally heated dust. In addition to rising an important point in itself, the Schöier and Jørgensen et al. works illustrate the paramount importance of correctly understanding the physical structure of the source to assess the chemical structure and all that follows.

For this reason, in the present work, we have re-analyzed the available data on IRAS16293 from scratch, considering, in addition, the most recent evaluation of the distance to this source by Loinard et al. (2008) (120 pc instead of 160 pc, as assumed in Ceccarelli et al., Schöier et al. and Jørgensen et al. works). This new analysis is necessary and timely because of two important observational projects having IRAS16293 as a target: a) the unbiased spectral survey in the 3, 2, 1 and 0.8 mm bands just obtained at the IRAM and JCMT telescopes (“The IRAS16293-2422 Millimeter And Sub-millimeter Spectral Survey” Caux et al. 2010, in prep.), and b) the unbiased spectral survey between 500 and 2000 GHz which will be obtained shortly with the heterodyne instrument HIFI aboard the Herschel Space Observatory (HSO) launched in May 2009 (the Guaranteed Time Key Program CHESS—Herschel space observatory (HSO) launched in May 2009 (the Herschel Guaranteed Time Key Program CHESS—Chemical Herschel Surveys of Star Forming Region)). The two projects, involving large international teams, will provide an accurate census of the molecular inventory of IRAS16293, the largest ever obtained in a solar type protostar. To convert the observations into an accurate chemical composition across the IRAS16293 envelope, the dust and gas density and temperature profiles have to be determined accurately first. Deriving these profiles is the goal of the present article.

We conclude this section by addressing the problem of the binarity of IRAS16293 and how it fits with the analysis we present here. As soon as interferometric observations became available it was realized that IRAS16293 is indeed a protobinary system (Wootten 1989; Mundy et al. 1992), composed by two sources: A (the south source) and B (the north source) separated by ~4", i.e. ~500 AU at 12 pc. While source B is the brightest in the continuum, source A is often, but not always, the brightest in the molecular emission (e.g. Chandler et al. 2003). The most recent observations show that IRAS16293 is indeed a triple system, with the source A composed by two objects, A1 and A2, of 0.5 and 1.5 M☉ respectively (Loinard et al. 2009). While it is clear that the multiple nature of IRAS16293 cannot be neglected in general, the two projects mentioned above involve observations with single-dish telescopes, so that much of the structure on small scales is smeared out in these observations.

Specifically, the molecular line emission will be dominated by the cold envelope, which fills up the telescope beam, and by any warm component at the interior of the envelope. The major goal here is to give a reliable estimate of the envelope temperature and density profiles of both the gas and dust components, up to the scales where the approximation of a spherical symmetry is valid. What are these scales will be discussed later on, based on the available observations.

The article is organized as follows. Section 2 discusses the derivation of the dust density and temperature distribution, based on the analysis of all available continuum data. Section 3 describes the derivation of the gas temperature profile, with the help of ISO data to constrain the abundance of a major gas coolant. Finally, Section 4 discusses and summarizes the results of the presented study.

2. Dust temperature and density profiles

2.1. The data set

The present analysis is based on the continuum emission from the envelope that forms/surrounds the protostar IRAS16293. Three types of observations are considered: maps of the emission, spectral energy distribution (SED) and interferometric observations at 1 and 3 mm. All data used have been retrieved from archives, except of the map at 350 µm and the 1 and 3 mm interferometric data that we obtained in dedicated observations. Below we briefly describe the data used.

i) Continuum emission profiles

We used the maps of the dust continuum emission at 350 µm (obtained at the Caltech Submillimeter Observatory; CSO), and 450 and 850 µm (obtained at the James Clerk Maxwell Telescope; JCMT).

The 450 and 850 µm maps have been retrieved from the JCMT archive (website). The beam sizes are 7.5′′ and 14.8′′ at 450 and 850 µm respectively. Based on the many previous JCMT published observations, the calibration uncertainty and noise levels are < 10% and 0.04 Jy beam−1 at 850 µm and ≤ 30% and 0.3 Jy beam−1 at 450 µm, respectively.

Observations of the 350 µm continuum emission toward IRAS 16293 reported here were carried out in 2003 February using the SHARC II facility bolometer camera of the Caltech Submillimeter Observatory (CSO) on Mauna Kea in Hawaii (Dowell et al. 2003). SHARC II is a 12 × 32 pixel filled array with a field of view of 2.6 × 1.0′. The data were taken during excellent submillimeter weather conditions (a 225 GHz zenith opacity of 0.04, corresponding to less than 1 mm of precipitable water). The observations were carried out using the “box-scan” scanning mode (see http://www.submm.caltech.edu/sharc). Five 10 min scans were reduced together using the CRUSH software package (Kovács 2008) to produce the final calibrated image. Telescope pointing was checked on Juno, Vesta, or Mars, immediately before or after the science observations and the measured offsets were applied during data reduction. The data were taken before the CSO Dish Surface Optimization system (DSOS) became operational. The shape of the telescope beam was determined from the pointing images of Vesta and Mars. It contains a diffraction limited main beam with a FWHM diameter of 9′′ and an error beam with a FWHM diameter of 22′′, with relative peak intensities of 0.8 and 0.2, respectively. This size of the error beam is consistent with earlier 350 µm measurements using the SHARC I camera (Huntten 1997).
Fig. 1. Continuum emission profiles at 850 $\mu$m (left bottom panel), 450 $\mu$m (right upper panel) and 350 $\mu$m (left upper panel), plus the SED (right bottom panel). The curves show the emission predicted by two models with different density profiles (see text for more details): the solid thick line is the best fit of the maps and SED data obtained by a density profile with a 2-indexes power law with $\alpha_{\text{out}}=2$ and $\alpha_{\text{in}}=1.5$ in the outer and inner envelope respectively (Shu-like density distribution); the dashed line is the best fit obtained by a single power-law index, $\alpha=1.8$. The dotted-dashed lines show the telescope beam profiles adopted.

We obtained continuum emission profiles as function of the distance from the center of the envelope, by averaging the map emission over annuli at the same distance. In each case we adopted a radial sampling corresponding to the half of the resolution of the instrument. The uncertainties of continuum emission profiles were evaluated taking into account the calibration uncertainty, noise levels and the non sphericity of the source. The resulting profiles, normalized to the peak emission, are shown in Fig. 1. Note that the 450 and 850 $\mu$m profiles are identical to those reported by Schöier et al. (2002).

ii) Spectral Energy Distribution

Table 1 reports the SED obtained considering all the data available in the literature (plus the 350 $\mu$m point obtained by us; see above). The millimeter and sub-millimeter data points have been obtained by integrating the maps over the entire envelope. The integrated flux at 1.3 mm was that quoted in Saraceno et al. (1996). We retrieved the IRAS fluxes from the IRAS Point Source Catalog v2.1 (http://irsa.ipac.caltech.edu/cgi-bin/Gator/nph-dd?catalog=iraspsc).

IRAS 16293 was observed with the InfraRed Spectrograph (IRS) installed aboard the Spitzer Space Telescope as part of the “From Molecular Cores to Planet Forming Disks” (Evans et al. 2003; Evans & c2d Team 2005) Legacy Program (AOR: 11826944, PI: Neal Evans). We use the observations obtained with the Long-High (LH) module (20-37 $\mu$m, $R=600$) on 2004 July 29, in staring mode. The data reduction was performed using the c2d pipeline S15.3.0 (Lahuis et al. 2006) with the pre-reduced (BCD) data. Since the MIPS map at 24 $\mu$m shows that the IRAS16293 emitting region ($\sim 30-40''$) is larger than the LH module field of view ($11.1'' \times 22.3''$), we adopted the full aperture extraction method in the pipeline. In addition, we corrected the derived flux level for the missing flux by comparing the IRS spectrum integrated on the MIPS bandwidth and the integrated MIPS flux. Note that this method assumes a similar distribution of the source emission in the whole IRS wavelength interval, $\sim 21-37 \mu$m. The correction factor derived by this method amounts to 22 % in the flux.

iii) Interferometric continuum data

| $\lambda$ ($\mu$m) | $F_\nu^a$ (Jy) | $\Delta F_\nu^b$ (Jy) | $\theta_{mb}^c$ (") | Ref. |
|-------------------|----------------|----------------------|---------------------|-----|
| 23.7              | 0.6            | 0.1                  | 6.0                 | 2   |
| 25                | 1.8            | 0.7                  | 80.0                | 3   |
| 60                | 255.           | 122.                 | 160.0               | 3   |
| 100               | 1032.          | 412.                 | 237.0               | 3   |
| 350               | 500.           | 250.                 | 90.0                | 1   |
| 450               | 270.           | 108.                 | 7.8                 | 1   |
| 850               | 20.2           | 8.                   | 14.5                | 1   |
| 1300              | 6.4            | 2.6                  | 22.0                | 4   |

Table 1. The Spectral Energy Distribution of IRAS 16293-2422. (a) Integrated flux in Jy. (b) Uncertainties in Jy considering the calibration uncertainty, the noise levels and the uncertainty on the source size. (c) Main beam of the instrument in arcsec.

Observations of the 3 and 1.3 mm continuum were obtained with the IRAM Plateau de Bure Interferometer (PdBI) in 2004 and are described in detail in Bottinelli et al. (2004). They were obtained in B and C configurations of the PdBI array, resulting in a spatial resolution of about 0.8″.

2.2. Adopted model

We obtained the best fit to the continuum data, described in the previous section, by using the 1D radiative transfer code DUSTY (Ivezic & Elitzur 1997), which has been extensively used in similar works (including Jørgensen et al. 2002, Schöier et al. 2002, 2004, Jørgensen et al. 2005). Briefly, giving as input the temperature of the central object and a dust density profile, DUSTY self-consistently computes the dust temperature profile and the dust emission. A comparison between the computed 350, 450, 850 μm brightness profiles (namely the brightness versus the distance from the center of the envelope) and SED with the observations (described in the previous section) allows to constrain the density profile and, consequently, the temperature profile of the envelope. To be compared with the observations, the theoretical emission is convolved with the beam pattern of the telescope.

Following the recommendations for the relevant telescope, the beam is assumed to be a combination of Gaussian curves: at 850 μm, the beam pattern of the telescope is assumed to be a combination of Gaussian curves: at 850 μm, the beam pattern of the telescope is

\[ y = \frac{r_{\text{out}}}{2m} \]

\[ n(r) = n(r_0) \left( \frac{r}{r_0} \right)^{\alpha} \quad r \leq r_{\text{in}} \]

\[ n(r) = n(r_0) \left( \frac{r}{r_0} \right)^{\beta} \quad r \geq r_{\text{in}} \]

where \( r_{\text{in}} \) is the radius of the collapsing envelope (at larger radii the envelope is static). In the density profile, it represents the radius at which the change of index occurs and it is a free parameter. Note that the complete Shu (1977) solution also contains a transition part at the interface of the collapsing and static regions, inside \( r_{\text{in}} \). In this region the slope gradually changes from \( r^{-1} \) to the limiting value of \( r^{-1.5} \). A posteriori, the effective part of the envelope in \( r^{-1} \) is relatively small and located in the inner region (\( \lesssim 1500 \) AU, equivalent to \( \sim 10″ \)). Since the continuum observations, with resolutions of \( \sim 8-18″ \), are not sensitive enough, we adopted the simplified structure described by the Eq. 12. In the second case, we considered a single power-law density profile, where the index \( \alpha \) is a free parameter:

\[ n(r) = n(r_0) \left( \frac{r}{r_0} \right)^{\alpha} \]

In both cases, \( n(r_0) \) is the density at \( r_0 \), and the envelope starts at a radius \( r_0 \) and extends up to \( r_{\text{out}} \). In total, both models have four free parameters determined by the best fit with the observational data: \( r_{\text{in}}, r_{\text{out}}, \alpha, \) and \( n(r_0) \). Finally, DUSTY requires the temperature of the central source, \( T_* \), here assumed to be 5000 K. Note that we verified that the choice of this parameter does not influence the results, as already noticed by other authors (e.g. Jørgensen et al. 2002). In practice, the DUSTY input parameters are the infall radius \( r_{\text{in}} \) or the power-law index \( \alpha \), the optical thickness at 100 μm, \( T_{100} \), the ratio between the inner and outer radius, \( Y = \frac{r_{\text{out}}}{r_{\text{in}}} \), and the temperature at the inner radius \( T_* \). The optical thickness is, in turn, proportional to \( n(r_0) \) and \( r_{\text{out}} \). In both models, we obtain a lower limit to \( T_{100} \) of 300 K, any larger value giving similar results.

In addition to the above parameters, the opacity of the dust as function of the wavelength is a hidden parameter of DUSTY. Following numerous previous studies (Van Der Tak et al. 1999; Evans et al. 2001; Shirley et al. 2002; Young et al. 2003; Schöier et al. 2002), we adopted the dust opacity calculated by Ossenkopf & Henning (1994), specifically their OH5 dust model, which refers to grains coated by ice. Again, the basic result, though, does not substantially depend on the choice of the dust opacity model.

As explained in Ivezic & Elitzur (1997), DUSTY gives scale-free results, so that the source bolometric luminosity \( L_{\text{bol}} \) and the distance are required to compare the DUSTY output with actual observations. We assumed here the latest estimate of the distance to the \( \rho \) Ophiuchus cloud, namely 120 pc (see Introduction), and we derived the bolometric luminosity by integrating the observed emission over the full spectrum, optimizing the resulting \( \chi^2 \) (see below).

We run grids of models for both cases described above. The summary of the covered parameter space is reported in Table 2.

| Parameter | Range   | Step |
|-----------|---------|------|
| \( \alpha \) | 0.2-2.5 | 0.1  |
| \( Y^n \) | 50-2000 | 10   |
| \( r_{\text{in}} \) | 5-200  | 2    |
| \( T_{100} \) | 0.1-10. | 0.1  |
| \( T_* \) | 300 K   | Fixed|
| \( T_{\text{in}} \) | 5000 K | Fixed|

Table 2. Range and step of the DUSTY input parameters.

The temperature at the inner radius \( T_{100} \), in fact defines the radius at which the integration starts. The DUSTY codes requires the temperature rather than the radius because it is based on a scale-free algorithm.

4 The temperature at the inner radius \( T_{100} \) affects the shape of the SED, so in general it enters in the determination of the bolometric luminosity.

5 Note that the dust optical thickness \( T_{100} \) depends mostly on the absolute density of the envelope. Note that we constrain also the bolometric luminosity based on the best fit of the SED.
Table 4. Integrated flux and Full Width at Half Maximum (FWHM) of the gaussians used to model the emission of the sources A and B at 1.3 and 3 mm.

| Source | F$_{\nu}$(Jy) | FWHM(’’) | F$_{\nu}$(Jy) | FWHM(’’) |
|--------|---------------|-----------|---------------|-----------|
| A      | 0.49          | 1.18      | 0.16          | 1.62      |
| B      | 0.97          | 0.86      | 0.25          | 0.78      |

The bolometric luminosity, obtained minimizing the $\chi^2$, is $22L_\odot$, rather then $14L_\odot$, the value obtained by simply scaling the bolometric luminosity adopted by Ceccarelli et al. (2000b) and Schöier et al. (2002) to a distance of 120 pc instead of 160 pc.

The single power-law and Shu-like density distributions can both reproduce the observations, the maps and the SED data, included the IR part of the spectrum (Figure 1). They give similar best fit $\chi^2$ values, although the Shu-like distribution fits better the $450\mu m$ profile. Also the derived physical parameters are substantially similar for the two models.

The observed data, including the Spitzer data between 20 and 40 $\mu m$, do not necessitate the presence of a large cavity (Jørgensen et al. 2005). Our solution with a larger luminosity (22 instead of $14L_\odot$) can reproduce as well the MIR Spitzer observations. Figure 2 shows the derived dust temperature and density profiles. Also the derived physical parameters are substantially similar for the two models.

Figure 3 shows the derived dust temperature and density profiles. The single power-law index density distribution predicts a slightly warmer and denser region at radii lower than about 100 AU, but the differences are relatively small (see also Table 3).

**b) Interferometric data analysis**

The previous analysis considers single dish data, which at best have a spatial resolution of 8’, equivalent to a radius of ~1000 AU. In order to constrain better the inner region, we used 1 and 3 mm continuum interferometric observations obtained with the Plateau de Bure interferometer (PdBI) described in the previous section. In order to compare the model predictions with the observations, we have produced synthetic maps for each model, in which we added the predicted emission from the envelope plus the emission of the two Gaussian-like sources A and B. The parameters used to represent the emission of the sources A and B are extracted from the interferometric maps at 1.3 and 3 mm and reported in Table 4. Then we used the UV_FMODEL task in GILDAS to compute visibility tables with the same $uv$ plane coverage than the actual observations.

Table 5 reports the $\chi^2_{red}$ values obtained using the observed and modeled visibility amplitudes at 1.3 mm. The comparison is done for each of the three models of the envelope, i.e. the single power-law density distribution, the Shu-like density distribution, and the central cavity of Schöier et al. (2004). We tested cases in which the envelope is centered on one of the two sources or on the mid-way point between the two sources. The $\chi^2_{red}$ values are computed over more than $10^4$ points. The 2D representation of the visibility amplitudes observed and modeled in $uv$ plan is difficult to read. Therefore to illustrate the comparison between the visibility amplitudes observed and modeled, we averaged the visibility amplitudes over the same $uv$ radius and plotted them in Figure 4. Note that the error bars shown in Fig. 4 represent only the measurement errors. In fact, the standard deviations resulting from the radial average are meaningless in this case because of the non-spherical geometry (caused by the presence of the sources A and B). Figure 4 only aims to illustrate the comparison between the observations and models, our conclusions will be based on the $\chi^2_{red}$ in Table 5. The computations were done considering all the visibility amplitudes obtained in the $uv$ plane before the azimuthal average.

The interferometric data are dominated by the two components of the IRAS16293 binary system. However, regarding the envelope contribution—which is relevant for the present work—in the case where the envelope is centered on the mid-way point between the sources A and B, the visibilities at $uv$ radii lower than about 80 k$\lambda$ are not well reproduced by the single power-law density profiles. Our solution with the Shu-like density profile and the solution with a cavity (suggested by Schöier et al. 2004) give a much better agreement. However, when envelope is centered on B or A all three models give similar results (Fig. 4), and fit well the observed visibilities. Since with the data available in the literature there is no way to know whether the envelope is centered on one of the two sources (A or B) or just on the mid-way point between them, either of the two solutions (centered on a source or on the mid-way point between A and B) is equally plausible. In other words, we are in a degenerated case dominated by the parameters relative to the binarity of the source. The interferometric data can be reproduced without a cavity. Note that the 3 mm PdBI observations do not provide additional information. We emphasize that the above analysis of the interferometric data is directly applicable to the OVRO data that led Schöier et al. (2004) to suggest the presence of a cavity. The OVRO data probe visibility amplitudes lower than about 60 k$\lambda$, a range also probed by the PdBI data. Therefore, as shown above, they can be reproduced by assuming that the envelope is centered on either A or B source without the necessity of assuming a cavity.

**c) Summary of the continuum data analysis**

Both the single dish and interferometric continuum data can be reproduced by either of the two models we considered: a Shu-like and single power-law density distribution. Furthermore, no cavity is required to explain the data, neither the Spitzer MIR data (Jørgensen et al. 2005) nor the interferometric data (Schöier et al. 2004).

Therefore, in the following we will adopt the Shu-like density profile (which has a physical interpretation), with no cavity, as our reference model for the study of the gas temperature and water line predictions.

**3. Gas temperature profile**

**3.1. Adopted method**

We computed the gas temperature profile using the CHT96 code described in Ceccarelli et al. (1996) (see also Ceccarelli et al. 2000a; Maret et al. 2002; Crimier et al. 2009). Briefly, the code computes the gas equilibrium temperature at each point of the envelope, by equating the heating and cooling terms at each point of the envelope. Following the method described in Ceccarelli et al. (1996), we considered heating from the gas
Nicolas Crimier et al.: The structure of the IRAS16293-2422 envelope

Table 3. Summary of the dust radiative transfer analysis. The upper half of the table lists the best fit parameters, the lower half reports some relevant physical quantities. The last column reports the results of the Schöier et al. (2002) analysis for comparison.

| Quantity                      | Shu-like model | Power-law model | Schöier et al. (2002) |
|-------------------------------|----------------|-----------------|-----------------------|
| $L_\ast$ ($L_\odot$)          | 22             | 22              | 27                    |
| $D$ (pc)                      | 120            | 120             | 160                   |
| $r_{out}$ (AU)                | 1280           | 2.0             | 4.5                   |
| $\tau_{100}$                  |                | 2.0             | 3.0                   |
| $r_{in}$ (AU)                 | 1280           | 1.8             | 1.7                   |
| $Y$                           | 280            | 260             | 250                   |
| Physical quantities          |                |                 |                       |
| $r_{in}$ (AU)                 | 22             | 27              | 32                    |
| $r_{out}$ (AU)                | 6100           | 6900            | 8000                  |
| $n(T_{dust}=100K)$ (cm$^{-3}$) | $2 \times 10^8$ | $3 \times 10^8$ |                       |
| $M_{env}$ ($M_\odot$)        | 1.9            | 2.1             | 5.4                   |

Fig. 2. MIR Spitzer and IRAS fluxes as a function of the wavelength. The two crosses represent the integrated fluxes at 23.7 and 25 $\mu$m obtained with MIPS aboard Spitzer and CPC aboard IRAS, respectively. The solid thick line is the IRS SPITZER spectrum observed between $\sim$ 21–37 $\mu$m (see text for details). The solid thin line is the best fit of the maps and SED data given by the model of envelope with a density profile with a broken power law with $\alpha_{out}=2$ and $\alpha_{in}=1.5$ in the outer and inner envelope respectively (Shu-like density distribution). The dashed line is the best fit given by the model of envelope with a single power-law index, $\alpha=1.8$. The dotted-dashed line and the dotted lines show the emission resulting from the models obtained by Jørgensen et al. (2005) and Schöier et al. (2002), respectively.

The cooling terms are the line emission from H$_2$O, CO and O. The dust-gas collisions are a source of heating when the dust temperature is higher than the gas temperature and a source of cooling elsewhere. To compute the cooling from the lines we used the code described in Ceccarelli et al. (1996, 2003) and Parise et al. (2005). The same code has been used in several past studies, whose results have been substantially confirmed by other groups (e.g. the analysis on IRAS16293-2422 by Schöier et al. 2002). Briefly, the code is based on the escape probability formalism in presence of warm dust (see Takahashi et al. 1983), where the escape probability $\beta$ is computed at each point by integrating the line and dust absorption over the solid angle $\Omega$ as follows:

$$\beta = \frac{k_d}{k_L + k_d} + \frac{k_L}{(k_L + k_d)^2} \int d\mu \frac{1 - \exp[-(k_L + k_d) \Delta L_{th}]}{\Delta L_{th}}$$  (4)

where $k_L$ and $k_d$ are the line and dust absorption coefficients respectively, and $\Delta L_{th}$ is the line trapping region, given by the following expressions:

$$\Delta L_{th} = 2\Delta v_{th} \left( \frac{v}{r} \right)^{1 - \frac{3}{2} \mu^2}$$  (5)

in the infalling region of the envelope (where $\arccos \mu$ is the angle with the radial outward direction) and in the static region (where $R_{env}$ is the envelope radius):

$$\Delta L_{th} = r \left( 1 - \frac{r}{R_{env}} \right)^{-1}$$  (6)

Compression (due to the collapse), dust-gas collisions and photo-pumping of H$_2$O and CO molecules by the IR photons emitted by the warm dust close to the center$^7$ is a minor heating term in the protostellar envelopes.
Fig. 3. Dust temperature (upper panel) and H$_2$ density (lower panel) profiles from the best fit obtained in the two cases Shu-like (solid line) and single power-law density distribution (dashed line).

In addition, H$_2$O and CO molecules can be pumped by absorption of the NIR photons emitted by the innermost warm dust. Since the densities and temperatures of the regions of the envelope targeted by this study are not enough to populate the levels in the vibrational states, the effect of the NIR photons is an extra heating of the gas, as described in Ceccarelli et al. (1996). Note that the code takes into account the dust with temperatures up to 1500 K.

The code has a number of parameters, that influence the gas equilibrium temperature. First, the dust temperature, assumed to be the output of the previous step analysis (§2). Second, since the infall heating depends on the velocity gradient across the envelope and the cooling depends on the gas lines (which can and are sometimes optically thick), the velocity field across the envelope is also a parameter of the code. Here we assumed that the infall velocity field corresponds to the free fall velocity field with a 2 M$_\odot$ source at the center of the envelope (Loinard et al. 2009). Third we adopted the “standard” cosmic rays ionization rate, namely $3 \times 10^{-17}$ s$^{-1}$, however, in practice this parameter is unimportant. Finally, given the contributions of the H$_2$O, CO and OI to the gas cooling, their respective abundances are important parameters of the model. Previous theoretical studies have shown that the O abundance is constant across the envelope, except in the very inner regions, where the gas temperature exceeds about 250 K and endothermic reactions that form OH and H$_2$O become very efficient (Ceccarelli et al. 1996; Doty & Neufeld...
Fig. 4. Visibility amplitudes as a function of the uv radius of the 1.3 mm PdBI observations (squares) against the predictions obtained with the best fit models of a Shu-like (solid lines) and single power-law (dashed lines) density distribution. The model of Schöier et al. (2004), with the central cavity, is shown for a comparison (dotted lines). Panels (a) and (b) show the case where the envelope is centered on the mid-way point between the sources A and B. Panels (c) and (d) show the case where the envelope is centered on the source B. Panels (a) and (c) show the visibility amplitudes modeled with the synthetic maps containing the contribution of the envelope and the sources A and B. Panels (b) and (d) show the visibility amplitudes modeled with the synthetic maps containing the contribution of the envelope only. Finally, the zero-signal expectation values are represented by the empty triangles on the c panel.

1997; Doty et al. 2004). Unfortunately, this parameter is very poorly constrained by observations (because of the difficulty of observing the O fine structure lines and the fact that they are easily excited in the foreground molecular cloud and its associated PDR (see e.g. Liseau et al. 1999; Caux et al. 1999). Here we assumed that the atomic O abundance is equal to $1 \times 10^{-5}$ and verified a posteriori that the O fine structure line emission is consistent with the ISO observations. We note, however, that O is never the dominant coolant except, perhaps, in a very small region of the envelope (Ceccarelli et al. 2000a, Maret et al. 2002). CO, in contrast, is the main coolant in the outer envelope, but, since the cooling lines are heavily optically thick, its abundance does not play an important role (in the regime where it is higher than about $1 \times 10^{-6}$ with respect to H$_2$). We, therefore, assumed a canonical $1 \times 10^{-4}$ CO abundance across the envelope.

Finally, water is an important coolant in the inner region, where the grain mantles sublimate, injecting into the gas phase large quantities of water molecules. Again, based on previous studies, we approximated the H$_2$O abundance with a step function: the abundance is $X_{in}$ in the region where the dust temperature exceeds 100 K, and $X_{out}$ elsewhere. Both $X_{in}$ and $X_{out}$ are found by comparing the theoretical predictions with the ISO observations (see §3.2). Note that, to solve the water level population statistical equilibrium equations, we used the collisional co-

---

8 Note that it possible that a region where CO abundance is lower, because of the freezing onto the dust grains, exists. However, the gas cooling is relatively insensitive to this lower abundance for the reasons explained in the text.
Finally, we assumed a H\textsubscript{2} Local Thermal Equilibrium (LTE) in each part of the envelope. In this computations, we used the dust temperature and density profiles of the Shu-like model of Table 3. We assumed that the ortho-to-para H\textsubscript{2} ratio is at the values recently computed by Faure et al. (2007). We assumed that the ortho-to-para H\textsubscript{2} ratio is at the Local Thermal Equilibrium (LTE) in each part of the envelope. Finally, we assumed a H\textsubscript{2} ortho-to-para ratio equal to 3.

### 3.2. Results

In order to constrain the water abundance, necessary to predict the gas temperature profile, we used the ISO observations of the H\textsubscript{2}O abundance in the inner region (where the ice sublimate), by the dust-gas collisions in a large intermediate region, and by the CO line emission in the very outer envelope. These results are very similar to those of Ceccarelli et al. (2000a). Note that low-lying water lines could possibly be contaminated by the outflow driven by the source. This effect could possibly lead to an overestimation of the outer water abundance. Since the ISO water lines are spectrally unresolved, it is not possible to address this question using the ISO data.

Tables 4 and 5 list the predicted fluxes of the water lines which will be observable with HSO, for the best fit model (H\textsubscript{2}O abundance in the outer envelope equal to 2.5 x 10\textsuperscript{-8}) with H\textsubscript{2}O abundance in the inner envelope equal to 0.5 x 10\textsuperscript{-7}, but also for the case with a larger H\textsubscript{2}O inner envelope abundance (2 x 10\textsuperscript{-7}).

### 4. Discussion and conclusions

The new analysis of the single dish and interferometric continuums observations of the envelope of IRAS16293 confirms that an envelope of about 2 M\textsubscript{\odot} surrounds the proto-binary system of IRAS16293. The envelope can be described with a Shu-like density distribution, corresponding to the gas collapsing towards a 2 M\textsubscript{\odot} central star. The luminosity of IRAS16293 has been re-evaluated to be 22 L\textsubscript{\odot} for a distance of 120 pc.

Both the single dish and interferometric data can be reproduced by an envelope with an inner radius between 20 and 30 AU, equivalent to about 0.4", and smaller than the radius at which the dust temperature reaches 100 K (the ice mantle sublimation temperature, namely 75 to 85 AU). We found that our new analysis can reproduce the full SED, including the Spitzer MIR data, without the necessity of a central cavity of 800 AU radius (Jørgensen et al. 2005). The difference between our models and the previous ones (based on the Schöier et al. 2002 initial model) is the larger bolometric luminosity (kept as a free parameter in our models) and the lower optical thickness of the envelope (τ \textsubscript{0.002μm} = 2, namely twice smaller than in the Schöier’s models). These differences contribute to make that the predicted...
MIR radiation flux agrees with the observed one. Finally, the interferometric data, being dominated by the two components of the binary system, do not provide significant constraints on the envelope structure, with one exception. They exclude the case of an envelope with a single power-law density profile centered on the mid-way point between the two sources. Based on this assumption, Schöier et al. (2004) suggested the presence of a cavity 800 AU in diameter. Since no data constrain where the center of the envelope is located, we favor the solution with the envelope centered on one of the two sources. In addition, the Shu-like model fits slightly better the PDBI data and is thus our preferred solution.

As already noted by Ceccarelli et al. (2000a), the ISO data do not allow to constrain the inner H$_2$O abundance because the detected lines are optically thick and cover a relatively low range of upper-level energies ($\lesssim 300 \text{ cm}^{-1}$). Also the outer-envelope water abundance is relatively poorly constrained. In addition, the relatively low spectral resolution of ISO does not allow to determine whether some lines are contaminated by the emission from the outflow. The future observations with the HIFI spectrometer aboard the Herschel Space Observatory, launched in May 2009, will certainly constrain better the water abundance profile across the IRAS16293 envelope, helping to understand the distribution of water in protostars similar to the Sun progenitor. On the one hand, the water abundance in the outer envelope ($0.7-20 \times 10^{-7}$) derived from the ISO observations here is consistent with some previous estimates of water abundance in cold gas (e.g. Cernicharo et al.1997) but only marginally consistent with other low estimates (e.g. Snell et al.2000), so the new Herschel/HIFI observations, with their largely improved spatial and spectral resolution, will be crucial in settling the question. On the other hand, the inner envelope abundance ($<2 \times 10^{-6}$) is lower than expected if all ice in the mantles sublimates (see Ceccarelli et al.2000a). Also in this case, the Herschel/HIFI observations will help to understand this point.

Finally, as stated in the Introduction, the major scope of the present work is to provide as accurate as possible estimates of the dust and gas temperature profiles of the cold envelope of IRAS16293 and its warm inner component, also known as the hot corino, to interpret the data observed in two large projects, TIMASSS and CHESS (see Introduction). We are aware that the proposed description has the intrinsic and clear limit of not taking into account the multiple nature of the IRAS16293 system. But it has the merit in allowing the interpretation of the single-dish observations of the upcoming projects, within this limitation. A more detailed analysis will only be possible once the relevant molecular emission is observed with interferometers, resolving the two components of the system. In absence of that, the analysis based on a single warm component and cold envelope is the only viable and allows a first understanding of the chemical composition of a system which eventually will form a star and planetary system like our own.

Acknowledgements. We warmly thank Laurent Loinard for the very useful discussions on the interferometric data of IRAS16293. We acknowledge the financial support by PPF and the Agence Nationale pour la Recherche (ANR), France (contract ANR-08-BLAN-0225). Fig. 8. Heating (top panel) and cooling (bottom panel) rates as function of the radius, computed assuming that the inner H$_2$O abundance is equal to $2 \times 10^{-6}$ and the outer H$_2$O abundance is $2.5 \times 10^{-7}$, for the Shu-like best fit model. The solid line shows the compression heating (top panel) and the OI line emission (bottom panel). The dust-gas collisions are represented by the dashed curves in both panels. The dotted curves show the contribution of the water molecules and the dotted-dashed curves that of the CO molecules, in both panels.
Table 5. $\chi^2_{\text{red}}$ values obtained comparing the visibility amplitudes observed and modeled at 1.3 mm. The number of degrees of freedom $\nu$ is 10230. The 1st column reports the $\chi^2_{\text{red}}$ obtained using the synthetic maps with the envelope centered on the mid-way point between the sources A and B. The 2nd and the 3rd columns report the $\chi^2_{\text{red}}$ obtained using the synthetic maps with the envelope centered on the source B and on the source A, respectively. The 1st, the 2nd, and the 3rd lines report the $\chi^2_{\text{red}}$ obtained in all the cases discussed in the text, using the model of envelope with a single power-law density distribution, a Shu-like density distribution, and a central cavity of [Schöier et al. (2004)], respectively.

| Model                  | $\chi^2_{\text{red}}$ | $\chi^2_{\text{red}}$ | $\chi^2_{\text{red}}$ |
|------------------------|------------------------|------------------------|------------------------|
| Single power-law       | 18.5                   | 10.2                   | 8.5                    |
| Shu-like               | 13.3                   | 10.3                   | 8.3                    |
| Central cavity         | 11.0                   | 11.3                   | 9.9                    |

$\chi^2_{\text{red}}$ is the reduced chi-squared, calculated as $\chi^2_{\text{red}} = \frac{\chi^2}{\nu}$, where $\chi^2$ is the chi-squared statistic and $\nu$ is the number of degrees of freedom.

Table 7. Predictions of the line fluxes (after subtraction of the continuum) of the water lines observable with the Herschel spectrometer PACS. The third (fourth) column reports the predictions computed assuming that the inner H$_2$O abundance is equal to $2 \times 10^{-6} (5 \times 10^{-8})$ and the outer H$_2$O abundance is $2.5 \times 10^{-7}$, for the Shu-like model best fit. The fifth column reports the observed ISO fluxes.
