Abstract

Background: To investigate the significant laboratory markers for early diagnosis of surgical site infection after spinal surgery. And determine the diagnostic cut-off values of these markers.

Methods: A total of 67 patients participated in the study: 11 patients who developed surgical site infection after spinal surgery (SSI Group) and 56 patients were compared with the infected group in terms of age, gender, operating time and intraoperative blood loss (Non-SSI Group). The white blood cell (WBC) count, WBC differential, C-reactive protein (CRP) and erythrocyte sedimentation rate (ESR) were determined before and 1, 3 and 7 days postoperatively. Then, we determine the diagnostic cutoff for these markers by using the receiver operating characteristic curve.

Results: The CRP, ESR and WBC were significantly higher in the SSI group at 3 and 7 days postoperatively. The lymphocyte ratio at 3 days postoperatively was significantly lower in the SSI Group. Using the receiver operating characteristic curve, lymphocyte ratio <11.5% at 3 days postoperatively (sensitivity 90.9%, specificity 75.4%, area under the curve [AUC] 0.919), and C-reactive protein level >26 mg/dL at 7 days postoperatively (sensitivity 90.9%, specificity 87.7%, area under the curve [AUC] 0.954) were the significant laboratory marker for early detection of SSI.

Conclusion: Lymphocyte ratio <11.5% at 3 days and C-reactive protein levels >26.5 mg/dL at 7 days after spinal surgery are reliable markers of SSI.

Background

With the increase of spinal surgery, surgical site infection (SSI), which was first described as a clinical entity by Turnbull in 1953, remains a common and costly complication of spinal surgery. SSI infection rates of 0.7 to 16% after instrumented spinal fusion have been reported. Complications associated with SSI after spinal surgery include pseudoarthrosis, deterioration of neurological function, sepsis, and even death.

When surgical site infection does occur, early diagnosis and treatment will greatly improve outcomes and shorten post-operative recovery. It should be based on indicators of systemic infection, laboratory data, imaging techniques, and local findings such as tenderness, swelling, redness, and purulent discharge to diagnose SSI. Of the clinical findings associated with SSI, there are several laboratory markers available for early detection because of their objectivity and convenience. For instance, C-reactive protein (CRP), erythrocyte sedimentation rate (ESR) and white blood cell (WBC) count and differential count.

Hence, we consider that reliable laboratory markers are needed for the early detection of SSI after spine decompression surgery. The present study aimed to identify the most significant laboratory marker and to determine an appropriate cut-off values for these diagnostic markers using receiver operating characteristic (ROC) curve for early detection of SSI.
Methods

The study protocol was approved by the institutional review board of Shaanxi Provincial People's Hospital (Clinical ethics committee of Shaanxi People's Hospital (2014), No.027.). We retrospectively reviewed 67 patients who underwent spinal surgery at the Department of Orthopedic Surgery, Shaanxi Provincial people's Hospital, between January 2015 and June 2018. SSI was determined according to U.S Centers for Disease Control and Prevention criteria. We recorded patients as SSI patients, if the surgeon performed debridement, conducted positive blood cultures, or drained surgical wounds. Patients were excluded if they had a trauma, tumor, or infection at the time of surgery or previous surgery of the lumbar spine, or were under 20 years of age. We also excluded patients who did not undergo laboratory tests on 1, 3 and 7 days after surgery.

We collected data include CRP, ESR, WBC count, and neutrophil and lymphocyte ratio before surgery and 1, 3, and 7 days postoperatively. CRP and ESR were measured by latex agglutination method, and WBC was measured by automatic cell counter. The ratio of neutrophils and lymphocytes was calculated from WBC percentage difference.

Statistical analyses were conducted using IBM SPSS 12.0 for Windows (Microsoft Corporation, Redmond WA). Data are expressed as mean ± standard deviations (SDs). Continuous variables are presented as means and standard deviations. Categorical variables are summarized as the number and percentage of the total study population. Normally distributed continuous variables were compared with a two-sided independent t-test. Categorical variables were combined with Chi-square. We determined appropriate diagnostic cutoffs of these selected markers using the ROC curve. Statistical significance was defined as P < 0.05.

Results

Demographics and Operative Circumstances

The final sample consisted of 67 patients and was divided into 11 patients who developed deep SSI (SSI group) and 56 who did not (non-SSI group). 7 male and 4 female were included in the SSI group, while 23 male and 33 female were in the non-SSI group. Mean age of patients in the SSI Group was 55.82±20.89 years and in the non-SSI group was 55.55±14.43 years. Operating time in the SSI group was 223.64±90.36 minutes (range 120~420), and in the non-SSI group was 189.74±80.70 minutes (range 60~450); intraoperative blood loss in the SSI group was 600.00±303.32ml (range 200~1000), and in the non SSI group was 442.11±251.21 ml (range 100~1000). There were no significant differences in the age, sex, operating time, and intraoperative blood loss between the two groups (Table 1).

Outcomes in the SSI Group

With the 11 SSI patients, 10 patients conducted debridement, 8 of them removed their instrumentation. The other 1 patient had antibiotics treated without surgery. In 10 patients who underwent reoperation, the
responsible bacteria (staphylococcus aureus in 4 cases, klebsiella pneumonia in 3 cases, pseudomonas aeruginosain 2 cases and 1 unknown) were detected at the surgical site.). The blood culture result of drug-treated patients is Staphylococcus aureus.

After surgery or medication treated all patients recovered (Table 2).

Biochemical Markers

There were no significant differences between the SSI and no-SSI groups for all chemical markers before surgery. Post-operative 1 day, the WBC count in the SSI group (15.65 ± 6.05) was significantly higher compared to the no-SSI group (12.07 ± 3.95) (t = –2.51, p = 0.01), but there was no significant differences in CRP, ESR, neutrophil ratio and lymphocyte ratio. (Fig.1)

Post-operative 3 day (Fig.2), the WBC count in the SSI group (12.55 ± 3.78) was no significant differences compared to the no-SSI group (10.29± 3.65) (t = –1.69, p = 0.096). The neutrophil ratio in the SSI group (0.84 ± 0.07) was significantly higher compared to the no-SSI group (0.75 ± 0.10) (t = –2.77, p = 0.007). The lymphocyte ratio in the SSI group (0.06± 0.03) was significantly lower compared to the no-SSI group (0.16 ± 0.06) (t = 4.94, p<0.001). The CRP in the SSI group (116.27 ± 72.84) was significantly higher compared to the no-SSI group (26.93 ± 23.16) (t = –7.64, p<0.001). The ESR in the SSI group (64.27 ± 26.67) was significantly higher compared to the no-SSI group (37.96 ± 24.28) (t = –3.24, p = 0.002).

Post-operative 7 day (Fig.3), there was no significant differences in the WBC count. The neutrophil ratio in the SSI group (0.79 ± 0.10) was significantly higher compared to the no-SSI group (0.72 ± 0.10) (t = –2.391, p = 0.020). The lymphocyte ratio in the SSI group (0.12 ± 0.07) was significantly lower compared to the no-SSI group (0.18 ± 0.09) (t = 2.267, p = 0.027). The CRP in the SSI group (118.27 ± 63.68) was significantly higher compared to the no-SSI group (17.68 ± 24.65) (t = –5.165, p<0.001). The ESR in the SSI group (63.91 ± 33.06) was significantly higher compared to the no-SSI group (36.46 ± 27.23) (t = –2.957, p = 0.004).

The ROC curve was used to determine the appropriate diagnostic cut-off values for important laboratory markers. The results are as follows: lymphocyte ratio 3 days postoperatively, cutoff <11.50% (sensitivity 90.9%, specificity 75.4%, area under the curve [AUC] 0.919; Figure 4.A)); CRP level 7 days postoperatively, cutoff = 26 mg/dL (sensitivity 90.9%, specificity 87.7%, area under the curve [AUC] 0.954; Figure 4.B).

Discussion

Although large-scale efforts have been initiated to help mitigate postoperative SSIs after spine surgery, a sizable burden still exists. The incidence of spinal SSI is between 0.7% and 16%, depending on the type of surgery and the area involved\textsuperscript{2,3}. The postoperative course complicated by SSI may entail long and repeated hospitalizations and multiple surgical interventions, including irrigation and debridement, removal of hardware, and complex wound closure. So early diagnosis and treatment would greatly improve results and shorten post-operative recovery.
However, not all patients can afford additional assessments (e.g. CT, MRI, PET) because these methods are very expensive and requires a lot of time\textsuperscript{13–15}. Therefore, postoperative laboratory markers are often used to screen SSI due to their objectivity, low cost and convenience\textsuperscript{12,16}.

The most widely used biochemical markers for early diagnosing SSI are CRP, ESR, and the WBC count and differential. The difference between ESR and CRP increases after surgery can distinguish between infected and non-infected patients. Larsson et al\textsuperscript{17} were the first to report changes in the CRP level in lumbar posterior lumbar surgery. they found that the level reached to peak on post-operative day 3, and dropped to normal (less than 10 mg/l) within 21 days after surgery. However, Takahashi et al\textsuperscript{18} reported that the postoperative CRP level peaked on day 2, and Aono et al\textsuperscript{19} reported that it peaked on day 4. The peak postoperative CRP levels should be between the 2nd and 4th day after surgery. It is believed that CRP levels have risen again or are still at peak levels 5 days after surgery, suggesting that SSI is more likely to occur.

In our result, we found that the level of CRP in the SSI group increased significantly 3 days after operation and remained high 7 days after operation. CRP in non-infectious group increased significantly 3 days after operation and decreased gradually 7 days after operation (Fig.1 D). ESR in infection group and non-infection group increased significantly 3 days after operation, but decreased slightly 7 days after operation(Fig.1 E). Erythrocyte sedimentation rate increased to peak levels about five days after surgery, followed by a slow and irregular decrease\textsuperscript{17}. Therefore, CRP is more suitable than ESR for evaluating infection. In our research, one day after operation, CRP increased in all patients. In non-SSI patients, CRP began to decline on days 3 and 7 after surgery. However, in infected patients, the third day after surgery increased further and decreased on the 7th day after surgery. We determine the diagnostic cutoff for CRP by using the receiver operating characteristic curve. If CRP is still > 26 mg/dl in 7 days after operation, infection should be highly suspected and antibiotics should be changed or increased.

Several factors have been reported in the literature that affect postoperative CRP levels, including blood loss, preoperative CRP levels, and spinal surgery segments. For example, surgery in the lumbar region is associated with higher postoperative CRP levels compared to surgery in other areas.\textsuperscript{20} Given the uncertainty of the use of inflammatory markers as a diagnostic tool for SSI, additional tools are needed to distinguish between infected and non-infected patients at the postoperative stage.

Takahashi et al\textsuperscript{21} reported for the first time that the WBC counts and lymphocyte counts are helpful for early diagnosis of surgical wound infections after lumbar surgery. In this article lymphocyte ratio no more than 10% or count less than 1,000/ L at 4 days after surgery indicates possible surgical wound infection. The authors suggest that lymphocytopenia represents an immunosuppressive state, indicating that the body’s susceptibility to infection increases, which may lead to the development of postoperative infection. After that, More and more scholars make a profound study at this field. Iwata et al showed that the lymphocyte count of <1,000/µL at 4 days postoperatively was the sole significant independent laboratory marker for early detection of SSI\textsuperscript{16}. Chao-Jun Shen et al reported\textsuperscript{22} that neutrophil/lymphocyte count ratio (NLR)at 4 and 7 days post-operation are valuable laboratory predictors for SSI in patients with posterior lumbar spinal surgery. ROC results showed that NLR> 5.19 at 4 days...
specificity of the NLR were 61.5% and 77.6%, the AUC was 0.708 and NLR> 3.85 at 7 days the sensitivity and specificity of the NLR were 69.2% and 62.7%; the AUC was 0.663.

In our result one day after surgical invasion, neutrophils increase and lymphocytes decrease in all patients. In non-SSI patients, neutrophils begin to decrease and lymphocytes increase on day 3 after surgery. However, in infected patients, further increase in neutrophils and decrease in lymphocytes were detected on day 3(Fig.1 B.C). Therefore, we determine the diagnostic cutoff for lymphocytes ratio by using the receiver operating characteristic curve. If the lymphatic ratio was less than 11.5% at 3 days after operation, and infection was highly suspected, which was similar to the previous literature. This may be an important indicator of SSI after posterior lumbar surgery.

Based on the results of the study, we analyzed the sensitivity and specificity of five laboratory indicators for early detection of SSI. There are two laboratory markers to be founded for its sensitivity and specificity. The first indicator was CRP level >26 mg/dl on day 7 after surgery, the sensitivity and specificity were 90.9% and 87.7%, the AUC was 0.954. the other indicator was lymphocyte ratio <11.50% on the third day after surgery. the sensitivity and specificity were 90.9% and 75.4%, the AUC was 0.919.

Our research has several limitations. First, this is a retrospective study. Therefore, there may be inherent bias associated with patient selection and missing patient information. Second, chronic SSI patients may be included in the non-SSI group because they only focus on the results of the hospitalization exam, which may reflect a serious underestimation of the actual number of SSI cases. In future studies, we will expand into the population and follow-up time, and hope to reduce these problem.

**Conclusion**

In conclusion, the lymphocyte ratio at 3 days postoperatively with a cutoff of <11.50%, and CRP level at 7 days postoperatively with a cutoff of >26 mg/dL, are the most reliable laboratory markers for early SSI following lumbar surgery, because they have a high sensitivity and can be measured early.
