Urea assisted ceria nanocubes for efficient removal of malachite green organic dye from aqueous system

Thupakula Venkata Madhukar Sreekanth, Patnamsetty Chidanandha Nagajyothi, Gutturu Rajasekhara Reddy, Jaesool Shim & Kisoo Yoo

This study describes a simple, high-yield, rapid, and inexpensive route for the synthesis of cubic shape-like cerium oxide nanocubes (CeO$_2$ NCs) using different urea concentrations (0.5, 1.0, and 2.0 g) by the hydrothermal method. The synthesized nanocubes (NCs) are labeled as CeO$_2$ NCs-0.5, CeO$_2$ NCs-1.0, and CeO$_2$ NCs-2.0, corresponding to 0.5, 1.0, and 2.0 g of urea, respectively. The synthesized NCs were characterized by FT-IR, UV-visible, XRD, XPS, SEM and HR-TEM analysis. The synthesized NCs were cubic in shape with average sizes of 12, 12, and 13 nm for the CeO$_2$ NCs-0.5, CeO$_2$ NCs-1.0, and CeO$_2$ NCs-2.0, respectively, obtained by the XRD analysis. The catalytic activity of the CeO$_2$ NCs was studied for the purpose of obtaining the reduction of malachite green (MG) in the presence of sodium borohydride (NaBH$_4$) at room temperature.

Environmental pollution is one of the most serious problems facing human beings and other life forms due to the increasing population, industrialization, and urbanization. Dyes are major pollutants that are released from textile industrial effluent. Malachite green (MG, including aniline green; basic green 4; diamond green B; and victoria green B) is a water-soluble cationic dye that is available in two forms malachite green chloride (C$_{23}$H$_{25}$ClN$_2$) and malachite green oxalate (C$_{52}$H$_{54}$N$_4$O$_{12}$) (Table 1). It is used as an industrial dye for the dyeing of leather, wool, silk, cotton, jute, paper and the manufacturing of printing inks and paints. The extensive usage of MG dye has caused several health problems, including significant effects on the immune and reproductive systems. MG also has the potential to cause genotoxic and carcinogenic effects and is extremely cytotoxic to mammalian cells, and hence the suitable treatment of wastewater containing MG dye is highly necessary. Several methods have been developed, such as physical, chemical, biological, and photocatalytic degradation methods for the treatment of industrial effluent. The physical and chemical methods include adsorption, ion-exchange, irradiation, oxidation processing, chemical precipitation, photolysis, coagulation/floculation, electrochemical treatment, ozonisation, photo-Fenton degradation, reduction and oxidation. The biological methods include fungal degradation, bacterial degradation, and aerobic and anaerobic degradation. However, these methods are generally expensive, are unable to completely remove the dye, and produce high sludge and by-products that cause secondary pollution. In recent years photocatalytic degradation of organic dyes has been used effectively, but this process is slow and energy-consuming. Compared with photocatalytic activity, a catalytic reduction is a relatively fast process without high energy requirements.

Ce is a rare earth element with a wide bandgap (~3.2 eV), lanthanide series, and exists as a free metal or oscillates between in the Ce$^{3+}$ and Ce$^{4+}$ oxidation states. CeO$_2$, NCs, also known as nanoceria, have been widely used in catalysis, fast-ion conductors, UV blockers, energy storage, and optical sensors due to its excellent physical and chemical properties. CeO$_2$ is an effective catalyst for the removal of organic dyes from effluents because ceria also hops between Ce$^{3+}$ and Ce$^{4+}$ valence states containing oxygen vacancies that allow NCs to act as regenerative catalysts. Various methods have been reported in the literature for the synthesis of ceria, including sol-gel, microwave combustion, flame spray pyrolysis, solvothermal, microemulsion, spray drying system, hydrothermal,
and thermal decomposition. Among these, the hydrothermal method is simple, which can produce high product yields.

In this study we synthesized CeO₂ NCs using urea (CH₄N₂O), as capping and reducing agent, urea was also known as carbamide and it is easily soluble in water. It has been used as a nitrogen source for the synthesis of environmentally benign nanoparticles. It has been widely used in many industries such as in agriculture, plastic, drug, soap, and detergent industries. However, excess concentrations urea in soil or in water causes to soil acidification and eutrophication and toxic effects to aquatic organisms, animals and humans. The ceria nanocubes (CeO₂ NCs) were synthesized via the one-pot hydrothermal method using different concentrations of urea. The CeO₂ NCs are applied as a catalyst for the degradation of MG in the presence of NaBH₄ in an aqueous medium using UV-visible spectroscopy.

Materials and Methods

Materials. Analytical grade cerium nitrate hexahydrate and urea were purchased from Alfa-Aesar, South Korea and used directly. Malachite green dye was obtained from Daejung Chemicals, South Korea. Deionized (DI) water was used throughout the study for the synthesis of CeO₂ NCs and dye degradation studies.

Synthesis of ceria nanocubes. Cerium nitrate hexahydrate, 0.01 M was prepared at a volume of 70 mL in DI water. Different quantities of urea (0.5, 1.0 and 2.0 g) were added and stirred until dissolved. This reaction mixture was transferred to an autoclave at a temperature of 180 °C for 6 h. The reaction solution was naturally cooled down to room temperature. The reaction mixture was carefully collected by centrifuge and wished with DI and ethanol to remove the unreacted substance, before drying at 80 °C overnight. This was later calcined at 400 °C for 4 h and for comparison we prepared ceria without urea (CeO₂ NCs-0.0).

Characterization. The crystallinity was measured by an X-ray diffractometer (PANalytical X-Pert PRO, USA) using a Cu Kα source (λ = 1.5405 Å). FT-IR (Perkin-Elmer, Bruker) was used to identify the vibrational modes by an ATR mode. The morphology of the samples was investigated by scanning electron microscopy (SEM-4800, Hitachi) and high-resolution transmission electron microscopy (TEM, Titan G2 ChemiSTM Cs Probe) with a 200 kV field emission gun in high brightness Schottky mode FEG (X-FEG). UV-visible absorption was measured on a Neogen (NEO-D3117). The elemental composition was quantitatively compared using an X-ray photoelectron spectrometer (K-alpha, Thermo Scientific, USA) with Al Kα radiation (1486.6 eV).

Catalytic activity. The synthesized samples were used to check the catalytic ability using the MG dye. For the catalytic reactions, 2.5 mL of the MG dye, 25 μL of well-dispersed CeO₂ NCs (2 mg/mL) and 0.2 mL of (0.2 M) freshly prepared NaBH₄ were added to all the samples. The degradation efficiency was monitored by UV-visible spectroscopy (Neogen, NEO-D3117). The degradation efficiency was calculated as a function of time for Co/Ct and ln Co/Ct, where Co is initial concentration and Ct is the final concentration of the MG dye. Blank control experiments were performed without catalyst (MG + NaBH₄) or NaBH₄ (MG + CeO₂ NCs) to study the catalyst efficiency.

Results and Discussion

Characterization. The UV-visible absorbance spectra of the ceria nanocubes are shown in Fig. 1. The synthesized ceria nanocubes exhibited broad absorption peaks below 400 nm. Couple of broad absorption peaks were observed at wavelengths 208 and 311 nm (CeO₂ NCs-0.5); 209 and 310 nm (CeO₂ NCs-1.0); and 209 and 314 nm (CeO₂ NCs-2.0). These peaks correspond to the characteristic absorption peaks of Ce³⁺ and Ce⁴⁺ of the CeO₂ NCs. These results are similar to those obtained by Nurhasanah et al. who observed absorption peaks at 207 and 303 nm for CeO₂ NCs (9 nm, precipitation method).

Fig. 2 shows the FT-IR spectra of the as-synthesized urea-based ceria nanocubes (CeO₂ NCs-0.5, CeO₂ NCs-1.0, and CeO₂ NCs-2.0). The features near 1540 and 1630 cm⁻¹ related to (νC=O) and (N-H stretching) bond stretch; the remaining observed peaks are as follows: near 3362 cm⁻¹ (O-H stretching vibrations); near 2980 cm⁻¹ (asymmetric C-H stretching); sharp band near 1340 cm⁻¹ (N-O stretch due to the presence of
Nitrate)\(^{-1}\); 1071 cm\(^{-1}\) (C-O stretching vibration)\(^{55}\); 850 cm\(^{-1}\) (formed by CeO\(_2\), which is typical peak of the Ce-O stretching vibrations)\(^{56}\); and below 700 cm\(^{-1}\) (O-Ce-O stretching vibrations)\(^{57}\).

Fig. 3 shows the XRD patterns of urea-based 0.5, 1.0 and 2.0 CeO\(_2\) NCs. The XRD revealed sharp peaks which located at \(2\theta = 28.5^\circ\), 32.9\(^\circ\), 47.5\(^\circ\), 56.3\(^\circ\), 59.0\(^\circ\), 69.3\(^\circ\), 76.7\(^\circ\), 78.8\(^\circ\), and 88.4\(^\circ\), are corresponding to (111), (200), (220), (311), (222), (400), (331), (420) and (422) planes, respectively. No extra peaks were observed, which supported the assumption that urea-based NCs are pure with cubic fluorite structure (JCPDC: 034–0394), similar peaks were also observed in CeO\(_2\) NCs-0.0 and results are shown in Fig. S1. The average mean grain size (MGS) of the NCs was calculated by the Debye-Scherer equation as follows\(^{58,59}\):

\[
MGS = 0.94\lambda/\beta\cos\theta
\]  

where \(\beta\) is the broadening in the full-width at half maximum (FWHM), \(\lambda\) is the X-ray wavelength (1.5406 Å), and \(\theta\) is the Bragg diffraction angle. The microstrain, \(\varepsilon\), of the NCs is evaluated by

\[
\varepsilon = (\beta \cos\theta)/4
\]
The dislocation density $\delta$, of the NCs is defined as the length of dislocations lines per unit volume and given by

$$\delta = \frac{1}{2\pi \rho}$$

(3)

The lattice strain (LS) of the NCs was calculated using the following relation:

$$LS = \frac{\beta}{4 \tan \theta}$$

(4)

From Table 2, the MGS increased with the increasing urea concentration, for CeO$_2$ NCs-0.5 and CeO$_2$ NCs-1.0 were showing similar value (12 nm), and for CeO$_2$ NCs-2.0 showing slightly bigger size (13 nm), whereas CeO$_2$ NCs-0.0 showing much higher than (31 nm) urea mediated CeO$_2$ NCs, this MGS analysis clearly indicating the urea was acted as capping and reducing agent to control the size of the NCs, meanwhile, the dislocation density decreased with increasing urea concentration, but for higher concentrations (CeO$_2$ NCs-1.0 and CeO$_2$ NCs-2.0) dislocation density was constant, in CeO$_2$ NCs-0.0 too low than the urea mediated CeO$_2$ NCs. The microstrain was constant with increasing urea concertation but without urea CeO$_2$ NCs showing lower than other CeO$_2$ NCs, however, lattice strain (LS) was constant for the first two concentrations (CeO$_2$ NCs-0.5 and CeO$_2$ NCs-1.0), and for the higher concentration (CeO$_2$ NCs-2.0), it was slightly lowered compared with those of the lower concentrations, whereas in CeO$_2$ NCs-0.0 showing very lower values, based on these results urea playing vital role as capping and reducing agent in the formation of CeO$_2$ NCs.

To identify the chemical composition on the surface of the CeO$_2$ NCs, we performed the XPS analysis (XPS analysis only for CeO$_2$ NCs-0.5) and the results are presented in Fig. 4. The survey scan (Fig. S2(a)) clearly shows the presence of Ce and O elements. The high-resolution XPS spectrum of Ce shown in Fig. 4a contains six peaks, revealing that the Ce contained both the Ce$^{3+}$ and Ce$^{4+}$ oxidation states. The binding energies (BE) at 882.9, 901.2 and 917.2 eV are attributed to Ce$^{4+}$, and the peaks at 885.5, 899.1 and 908.3 eV are the characteristic peaks of Ce$^{3+}$. These results suggest the presence of mixed oxidations and a valence state for the Ce ions in the NCs and Deshpande et al. reported that Ce$^{3+}$ ions create oxygen vacancies in the CeO$_2$ lattice that are defects. There were three peaks in the high-resolution O 1s deconvoluted spectrum in Fig. 4b; the O1 peak, O2 peak, and O3 peak, with 529.8, 532.0, and 533.6 eV binding energies, respectively. The O1 peak (529.8 eV) corresponds to the bond Ce-O, O2 peak (532.0 eV) is attributed to the oxygen vacancies, and O3 peak (533.6 eV) belongs to organic C=O bond or surface –OH groups. To get more information we performed XPS analysis for N 1 s, but the results are not showing any significant peak for N 1 s and results are shown in Fig. S2(b). These results are indicating the urea was acting as capping and reduction the formation of CeO$_2$ NCs, not doped in CeO$_2$ NCs, which are similar to the values in literature.

The morphology of CeO$_2$ NCs was obtained by SEM, and the images are revealed in Fig. 5. For CeO$_2$ NCs-0.5, CeO$_2$ NCs-1.0, and CeO$_2$ NCs-2.0, SEM images show that aggregates were formed by the accumulation of nanocubes. SEM images of CeO$_2$ NCs-0.0 was shown in Fig. S3, the results are indicating that the CeO$_2$ NCs-0.0 were more in aggregation and size also higher than the urea mediated CeO$_2$ NCs. The details of CeO$_2$ NCs were further confirmed by HR-TEM studies. Fig. 6 shows the HR-TEM images of CeO$_2$ NCs synthesized with different concentrations of urea. The TEM images show that CeO$_2$ NCs were well dispersed, almost polydispersed, consisting of cubic shapes. The CeO$_2$ NCs obtained with 0.5 urea-based NCs were smaller in size and less aggregated.
compared with the 1.0 and 2.0 urea-based NCs. To confirm the phase formation of the NCs, HR-TEM images were analyzed using the Gatan software, and the results are shown in Fig. 6a–iv–c–iv for CeO$_2$ NCs-0.5, CeO$_2$ NCs-1.0, and CeO$_2$ NCs-2.0, respectively. The lattice fringe distance values were similar, 0.307 nm for CeO$_2$ NCs-0.5, 0.307 nm for CeO$_2$ NCs-1.0 and 0.306 nm CeO$_2$ NCs-2.0, and were assigned to the (111) plane of the CeO$_2$ NCs. The corresponding selected area electron diffraction (SAED) pattern (Fig. 6a–v, b–v and c–v for CeO$_2$ NCs-0.5, CeO$_2$ NCs-1.0, and CeO$_2$ NCs-2.0) shows well-defined diffraction rings that confirm the polycrystalline nature of CeO$_2$ NCs. These results were in good agreement with the XRD results. Therefore, the HR-TEM images revealed a good crystalline nature of the urea assisted NCs.

**Catalytic activity.** MG dye was selected as a model pollutant to examine the catalytic activity of CeO$_2$ NCs in the presence of NaBH$_4$ as the reducing agent under ambient conditions. The results are presented in Fig. 7a to c for CeO$_2$ NCs-0.5, CeO$_2$ NCs-1.0, and CeO$_2$ NCs-2.0, respectively. Fig. 7d shows a comparison of the absorption
spectra of the catalytically degraded MG after 21 min in the presence of catalyst and NaBH₄. The MG maximum absorption peak intensity was at ~617 nm. The intense green color of the MG dye solution slowly faded becoming colorless, during the catalytic dye degradation process. A plot of $C_0/C_t$ versus degradation, time is shown in Fig. 8a for all samples, where $C_0$ is initial concentration and $C_t$ is concentration at time ‘t’.

Langmuir-Hinshelwood pseudo-first order kinetics was applied to determine the first-order rate constant for dye degradation using the following relation:

$$k = -\ln(C_0/C_t)$$  

where ‘k’ is the rate constant (min⁻¹) of the dye degradation reaction, $C_0$ is the initial concentration and $C_t$ is the concentration of the dye solution after time ‘t’ in minutes, respectively. The results are shown in Fig. 8b. To identify the role of catalyst, we performed two control experiments. In the first experiment we performed the reaction between NaBH₄ + CeO₂ NCs and in the second experiments, we performed the reaction between dye (MG) + NaBH₄, respectively. In both these control experiments, there was no observed degradation, based on these control experimental results we confirmed that the catalyst (CeO₂ NCs) playing a vital role in the dye decolorization, and when both the catalyst + NaBH₄ were together, the degradation materialized rapidly; the results are shown in Fig. 7a. The CeO₂ NCs-0.5 exhibited an excellent dye degradation ~90%, while the CeO₂ NCs-1.0 and CeO₂ NCs-2.0 exhibited ~70% MG dye degradation within 21 min. The possible mechanism of dye reduction by the catalyst is explained by the electron relay system. The NCs start the catalytic reduction by relaying electrons from the donor BH₄⁻ to the dye molecules (acceptor), where the catalyst (NCs) accepted electrons from nucleophilic BH₄⁻ ions and transferred them to electrophilic dyes. Saikia et al. described hydrogen species generated from BH₄⁻ ions attack the dye (MG) molecules after electron transfer to nanocubes. This reaction leads to a reduction in the MG dye, which is generally leuco MG (colorless). The CeO₂ nanocatalysts show slope of ~0.127, ~0.061 and ~0.064 for CeO₂ NCs-0.5, CeO₂ NCs-1.0, and CeO₂ NCs-2.0, respectively. The rate constants for dye degradation were 0.127 min⁻¹, 0.061 min⁻¹, and 0.064 min⁻¹ for CeO₂ NCs-0.5, CeO₂ NCs-1.0, and CeO₂ NCs-2.0, respectively (Fig. 8a,b). CeO₂ NCs-0.5 exhibited the highest dye degradation due to their size and high dispersion. We evaluated the catalytic activity of the CeO₂ NCs-0.0, the rate constant was 0.03 min⁻¹, as shown in Fig. S3 and it has shown poor performance than CeO₂ NCs-1.0 and 2.0 that of counterparts due to bigger size and aggregation of particles.
Conclusion

We developed cost-effective CeO₂ NCs using carbamide by one-pot hydrothermal method. The HR-TEM images revealed the synthesized NCs was cubic in shape. XRD results show the synthesized nanoparticles MGS of 12, 12, 13 and 31 nm for CeO₂ NCs-0.5, CeO₂ NCs-1.0, CeO₂ NCs-2.0 and CeO₂ NCs-0.0, respectively. These results were indicating that urea acting as capping and reducing agent. The synthesized CeO₂ NCs also acted as efficient catalysts in the degradation of the MG dye.

Acknowledgements
This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-2017R1C1B2001990) and 2017 Yeungnam University Research Grant.

Author Contributions
The manuscript was written through the contributions of all authors. T.V.M.S.K., P.C.N.J. and G.R.R. conducted the synthesis, characterization, and application. J.S. and K.Y. designed and supervised the project.
