Abstract

We propose a formalization of the three-tier causal hierarchy of association, intervention, and counterfactuals as a series of probabilistic logical languages. Our languages are of strictly increasing expressivity, the first capable of expressing quantitative probabilistic reasoning—including conditional independence and Bayesian inference—the second encoding do-calculus reasoning for causal effects, and the third capturing a fully expressive do-calculus for arbitrary counterfactual queries. We give a corresponding series of finitary axiomatizations complete over both structural causal models and probabilistic programs, and show that satisfiability and validity for each language are decidable in polynomial space.

Introduction and Summary

Intelligence commonly involves prediction, anticipating future events on the basis of past observations (e.g., “Will the water pipes freeze again this winter?”). Intelligent planning and decision-making additionally require predicting what would happen under a hypothetical action (“Will the pipes freeze if we keep the heat on?”). An even more sophisticated ability—critical for tasks like explanation—is to reason counterfactually about what would have happened given knowledge about what in fact happened (“Would the pipes have frozen if we had left the heat on, given that the heat was off and the pipes in fact froze?”). These three modes of reasoning constitute a causal hierarchy (Shpitser and Pearl 2008; Pearl 2009), highlighting the significance of structural causal knowledge for flexible thought and action.

The aim of the present article is to gain conceptual as well as technical insight into this hierarchy by employing tools from logic. Loosely following earlier work (Shpitser and Pearl 2008), we propose a characterization of its levels in terms of logical syntax. Semantically, all three languages are interpreted over the same class of models, namely structural causal models (and later probabilistic programs). The languages differ in how much they can express about these models. \( L_1 \), the language of association, expresses only “pure” probabilistic facts and relationships; \( L_2 \), the language of probabilistic intervention, allows expressing probabilities of basic conditional “if...then...” statements; \( L_3 \), the language of probabilistic counterfactuals, encodes probabilities for arbitrary boolean combinations of such conditional statements. Using standard ideas from logic and existing results, we can address questions about definability and expressiveness. For instance, it is easy to prove in our framework that each language is strictly more expressive than those below it in the hierarchy (Prop. 1, 2 below). We can also interpret well-known insights from the graphical models and causal learning literatures as graph definability results for appropriate probabilistic logical languages, analogously to correspondence theory in modal logic (van Benthem 2001).

In possession of a precise syntax and semantics for probabilistic causal reasoning, questions of axiomatization naturally arise. That is, we would like to identify a perspicuous set of basic principles that underly all such reasoning. One of our main technical contributions is a series of finitary (sound and complete) axiomatizations for each level of the causal hierarchy (Thm. 5), relying on methods from semialgebraic geometry. As a corollary to these completeness results, we also reveal a “small-model property” with the consequence that satisfiability and validity for \( L_1 \), \( L_2 \), and \( L_3 \) can be decided in polynomial space (Thm. 11).

Finally, in the last part of the paper we consider an alternative interpretation for our three logical languages. Probabilistic programs, with an appropriate notion of causal intervention, provide a procedural semantics for probabilistic counterfactual claims and queries. We establish an equivalence between these models and a natural subclass of computable structural causal models (Thm. 12). The equivalence in turn implies soundness and completeness of our axiomatizations with respect to this interpretation as well.

Relation to Previous Work

While deterministic causal counterfactuals and probabilistic logics have both received extensive treatment independently, the present contribution appears to be the first systematic study of probabilistic counterfactuals. Our work thus synthesizes and improves upon a long line of previous work. Axioms for causal conditionals interpreted over structural causal models are well understood (Galles and Pearl 1998; Halpern 2000; Pearl 2009; Zhang 2013; Ibeling and Icard 2020).
We are interested in structural causal models (Spirtes, Glymour, and Scheines 2000; Pearl 2009) defined over a set \( \mathcal{X} \) of endogenous variables and a set \( \mathcal{U} \) of exogenous variables; let the combined variable set be \( \mathcal{V} = \mathcal{X} \cup \mathcal{U} \). Every variable \( V \in \mathcal{V} \) takes on a value from an admissible set \( \text{Val}(V) \). While \( \mathcal{X} \) and \( \mathcal{U} \) may be infinite, we assume \( \text{Val}(\mathcal{X}) \) is finite for all \( X \in \mathcal{X} \).

**Definition 1 (Structural Causal Model).** We define a SCM to be a pair \( \mathfrak{M} = (\mathcal{F}, P) \), where \( P \) is a probability measure on a \( \sigma \)-algebra \( \Sigma \) of settings \( u \) of \( \mathcal{U} \), and \( \mathcal{F} = \{ f_X \}_{X \in \mathcal{X}} \) is a set of functions, one for each endogenous variable.

Given a set of variables \( \mathcal{V}' \subseteq \mathcal{V} \), we call an assignment of each variable \( V \in \mathcal{V}' \) to a value in \( \text{Val}(V) \) a setting. Thus every \( f_X \) is a function from settings \( \mathfrak{r} \) of endogenous variables \( \mathcal{X} \) and settings \( u \) of exogenous variables \( \mathcal{U} \) to a value \( f_X(\mathfrak{r}, u) \in \text{Val}(X) \). \( P(\mathcal{U}) \) and \( \mathcal{F} \) thus define the obvious joint probability distribution \( P_{\mathfrak{M}}(\mathcal{X}) \).

**Definition 2 (Intervention).** An intervention is a partial function \( i : \mathcal{X} \rightarrow \text{Val}(X) \). It specifies variables \( \text{dom}(i) \subseteq \mathcal{X} \) to be held fixed, and the values to which they are fixed. Intervention \( i \) induces a mapping of SCMs, also denoted \( i \), so that \( i(\mathfrak{M}) \) is identical to \( \mathfrak{M} \), but with \( f_X \) replaced by the constant function \( f_X(\cdot) = i(X) \) for each \( X \in \text{dom}(i) \). We say \( i \) is finite whenever \( \text{dom}(i) \) is finite.

Using this definition we introduce a relation of direct causal influence (Halpern and Pearl 2005). We say \( X \rightarrow Y \) when there are endogenous settings \( \mathfrak{r}_1, \mathfrak{r}_2 \) differing only in their assignment to \( X \), and an exogenous setting \( u \) such that \( f_Y(\mathfrak{r}_1, u) \neq f_Y(\mathfrak{r}_2, u) \). This in turn induces a dag \( \mathfrak{G}_{\mathfrak{M}} = (\mathcal{X}, \rightarrow) \). Throughout we restrict attention to SCMs \( \mathfrak{M} \) such that \( \mathfrak{G}_{\mathfrak{M}} \) is well-founded, generalizing the common acyclicity condition. This is also equivalent to the requirement for infinite SCMs from (Ibeling and Icard 2019).

We say \( \mathfrak{M} \) is Markov if each variable is \( P_{\mathfrak{M}} \)-independent of its non-descendants (in \( \mathfrak{G}_{\mathfrak{M}} \)) conditional on its parents. The Markov condition is guaranteed provided the exogenous variables \( \mathcal{U} \) are jointly independent (Pearl 2009, Thm. 1.4.1). We define \( d \)-separation on a dag \( \mathfrak{G} \) standardly, and write \((X \perp \perp Y | Z)_{\mathfrak{G}} \) to say that the variables \( X \) and \( Y \) are \( d \)-separated from \( Y \) given \( Z \). In Markov structures \( d \)-separation guarantees conditional independence.

In order to establish a correspondence (Thm. 12) with probabilistic programs, we introduce a further restriction on SCMs, following previous work on computable causal models (Janzing and Schölkopf 2010; Ibeling and Icard 2019). Def. 3 below assumes a very simple “coin-flip” probability space; we leave it as an exercise to show that there is no loss of generality compared to using any computable probability space as in, e.g., (Ackerman, Freer, and Roy 2019), including any standard continuous probability distributions.

**Definition 3.** \( \mathfrak{M} = (\mathcal{F}, P) \) is computable if (1) its exogenous variables consist of infinitely many binary \( U_1, U_2, \ldots \), each uniformly distributed by \( P \), and (2) the collection \( \mathcal{F} = \{ f_X \}_{X \in \mathcal{X}} \) is uniformly computable (Weihrauch 2000).

Call a model \( \mathfrak{M} = (\mathcal{F}, P) \) measurable if under every finite intervention \( i \), the joint distribution \( P_{i(\mathfrak{M})}(X) \) is well-defined. The next Fact is straightforward.

**Fact 1.** A computable SCM is both Markov and measurable.

*Proof.* A computable \( \mathfrak{M} = (\{ f_X \}_{X \in \mathcal{X}}, P) \) is Markov simply because all exogenous variables are jointly independent. Let \( \mathfrak{r} \) be an endogenous setting and let \( u = \bigcap_{X \in \mathcal{X}} u_X \) where \( u_X = \{ u : f_X(\mathfrak{r}, u) = f_X(\mathfrak{r}) \} \). Letting \( \Sigma \) be our \( \sigma \)-algebra, \( P_{i(\mathfrak{M})}(\mathfrak{r}) \) is well-defined if \( u \in \Sigma \). It suffices to show that \( u_X \in \Sigma \) for all \( X \) since \( \Sigma \) closes under countable intersection. There is a machine that halts outputting the value \( f_X(\mathfrak{r}, u) \) for any \( u \in u_X \). By then it has seen only finitely many exogenous bits, whose values we write in a finite vector \( \vec{u}(u) \). Thus the cylinder set \( C(\vec{u}(u)) \) of \( u \) that agree with
\[ u'(u) \text{ wherever the latter is defined is contained in } u_X. \] So letting \( u_X' = \bigcup_{u \in \Sigma} C(u'(u)), u_X \subseteq u_X'. \) Every cylinder is in \( \Sigma \) and there are only countably many cylinders, so \( u'_X \in \Sigma; \) obviously \( u_X \subseteq u'_X \) so \( u_X \in \Sigma \) as desired.

Let \( M \) be the class of all measurable SCMs that have a well-founded causal influence graph. Further, let \( M' \) be the subclass of computable models in \( M. \)

### Probabilistic Conditionals

**Syntax**

We define a succession of language fragments as follows, where \( X \in \mathcal{X} \) and \( x \in \text{Val}(X): \)

\[
\begin{align*}
\mathcal{L}_{\text{int}} &::= \top \mid X = x \mid \mathcal{L}_{\text{int}} \land \mathcal{L}_{\text{int}} \\
\mathcal{L}_{\text{prop}} &::= X = x \mid \neg \mathcal{L}_{\text{prop}} \mid \mathcal{L}_{\text{prop}} \land \mathcal{L}_{\text{prop}} \\
\mathcal{L}_{\text{cond}} &::= [\mathcal{L}_{\text{int}}] \mathcal{L}_{\text{prop}} \\
\mathcal{L}_{\text{full}} &::= [\mathcal{L}_{\text{cond}}] \neg \mathcal{L}_{\text{full}} \mid \mathcal{L}_{\text{full}} \land \mathcal{L}_{\text{full}}
\end{align*}
\]

Based on these fragments we define a sequence of three increasingly expressive probabilistic languages \( \{\mathcal{L}_i\}_{i=1,2,3}. \) Each language \( \mathcal{L}_i \) speaks about probabilities over the base language \( \mathcal{L}_{i}^{\text{base}}. \) The base languages are

\[
\mathcal{L}_{i}^{\text{base}} = \mathcal{L}_{\text{prop}}, \quad \mathcal{L}_{i}^{\text{base}} = \mathcal{L}_{\text{cond}}, \quad \mathcal{L}_{i}^{\text{base}} = \mathcal{L}_{\text{full}}.
\]

Our languages describe facts about the probabilities that base language formulas hold. As our formulas are finitary, such facts correspond to polynomials in these probabilities. Let us make this precise. Fixing a set \( V, \) define the polynomial terms in the variables \( V \) to be the \( t \) generated by this grammar (where \( V \) generates any element of \( V \)): \[
\begin{align*}
t &::= V \mid t + t \mid t \cdot t \mid - t.
\end{align*}
\]

Then the terms of \( \mathcal{L}_i \) are polynomials over probabilities of base formulas, i.e., polynomial terms in the variables \( \{P(\phi) : \phi \in \mathcal{L}_{i}^{\text{base}}\}. \) The language \( \mathcal{L}_i, i = 1, 2, 3, \) is then a propositional language of term inequivalences:

\[
\mathcal{L}_i ::= t \geq t \mid - \mathcal{L}_i \mid \mathcal{L}_i \land \mathcal{L}_i
\]

where \( t \) is a term of \( \mathcal{L}_i. \) We employ the following abbreviations. For \( \mathcal{L}_{\text{prop}} \) and \( \mathcal{L}_{\text{full}} \) we take \( \bot \) to stand for any propositional contradiction, and \( \top \) for any propositional tautology. For terms: \( \emptyset \) for \( P(\bot) \), \( \mathbf{1} \) for \( P(\top) \). For \( \mathcal{L}_1 \) formulas, we write \( t_1 \equiv t_2 \) for \( (t_1 \geq t_2) \land (t_2 \geq t_1), \) and \( t_1 > t_2 \) for \( (t_1 \geq t_2) \land - (t_2 \geq t_1). \) Note that we may use any rational number as a term via representing its numerator as a sum of \( 1/\mathbb{N} \)s and clearing its denominator through an inequality \( t \geq t, \) and we write \( q \) for a rational \( q \) thus considered as a term.

**Semantics**

A model is simply a measurable SCM \( \mathfrak{M} = (\mathcal{F}, P). \) Since \( \mathfrak{M} \) is well-founded, each \( u \) determines the values of all endogenous variables. Thus, for \( \phi \in \mathcal{L}_{\text{prop}} \) we will write \( \mathcal{F}, u \models \phi, \) defined in the obvious way. For \( \alpha \in \mathcal{L}_{\text{int}} \) we define the intervention operation \( i_{\alpha} \), so that \( i_{\alpha}(\mathcal{F}) \) is the result of applying the interventions specified by \( \alpha \) to \( \mathcal{F} \) (Def. 2). Then we say \( \mathcal{F}, u \models [\alpha] \beta \) just in case \( i_{\alpha}(\mathcal{F}), u \models \beta. \) We have thus defined \( \mathcal{F}, u \models \phi \) for all \( \phi \in \mathcal{L}_{\text{full}}. \)

Finally, for any \( \phi \in \mathcal{L} \) and model \( \mathfrak{M} \) define the set \( S_{\mathfrak{M}}(\phi) = \{ u : \mathcal{F}, u \models \phi \}. \) Measurability of \( \mathfrak{M} \) guarantees that \( S_{\mathfrak{M}}(\phi) \) is always measurable. Toward specifying the semantics of \( \mathcal{L}_1 \) we define \( [t]_{\mathfrak{M}} \) recursively, with the crucial clause given by \( [P(\phi)]_{\mathfrak{M}} = P(S_{\mathfrak{M}}(\phi)). \) Satisfaction of \( \phi \in \mathcal{L}_i \) is as expected: \( \mathfrak{M} \models t_1 \geq t_2 \) iff \( [t_1]_{\mathfrak{M}} \geq [t_2]_{\mathfrak{M}}, \) \( \mathfrak{M} \models \neg \phi \) iff \( \mathfrak{M} \models \phi \land \psi \) iff \( \mathfrak{M} \models \phi \) and \( \mathfrak{M} \models \psi. \) As in previous work, it is easy to see that none of the languages \( \mathcal{L}_1, \mathcal{L}_2, \mathcal{L}_3 \) is compact (Perović et al. 2008; Ibeling and Icard 2018; 2019); consequently Thm. 5 shows weak completeness only.

**Comparing Expressivity**

With a precise semantic interpretation of our three languages in hand, we can now show rigorously that they form a strict hierarchy, in the sense that models may be distinguishable only by moving up to higher levels of the hierarchy.

**Proposition 1.** \( \mathcal{L}_2 \) is strictly more expressive than \( \mathcal{L}_1. \)

**Proof.** Consider \( \mathcal{M}_1 \) with \( U \sim \text{Bernoulli}(0.5) \) and \( X := U \) while \( Y := X; \) in \( \mathcal{M}_2 \) we have \( Y := U \) and \( X := Y. \) It is easy to see by an induction on terms in \( \mathcal{L}_1 \) that \( [t]_{\mathcal{M}_1} = [t]_{\mathcal{M}_2} \), and thus \( \mathcal{M}_1 \) and \( \mathcal{M}_2 \) validate the same \( \mathcal{L}_1 \) formulas. Yet, \( \mathcal{M}_1 \models [X = 1] Y = 1 \equiv \mathbf{1} \), while \( \mathcal{M}_2 \models [X = 1] Y = 1 \equiv \mathbf{1} \). In particular the schema \( P(\beta \alpha) \equiv P(\alpha \beta) \) is also falsified by \( \mathcal{M}_2, \) a reflection of the distinction between observation and intervention.

**Proposition 2.** \( \mathcal{L}_3 \) is strictly more expressive than \( \mathcal{L}_2. \)

**Proof.** Consider an example adapted from (Avin, Shpitser, and Pearl 2005) with two endogenous and two exogenous variables \( X, U_X, Y, U_Y, \) where \( U_X \sim \text{Bernoulli}(0.5) \) and \( X = U_X, \) while \( U_Y \sim \text{Unif}(0,1,2). \) The difference between models \( \mathcal{M}_1 \) and \( \mathcal{M}_2 \) is the equation for binary variable \( Y. \) In \( \mathcal{M}_1 \) we have \( Y \) equal to \( (X \leftrightarrow U_Y) = 0, \) and in \( \mathcal{M}_2 \) we have \( Y \) given by \( (X \rightarrow U_Y) = 0 \land (U_Y = 2 \rightarrow X). \) It is then easy to check (by induction) that \( \mathcal{M}_1 \) and \( \mathcal{M}_2 \) validate all the same \( \mathcal{L}_2 \) formulas, whereas, e.g., \( P[U_{\mathcal{M}_1}] \neq P[U_{\mathcal{M}_2}], \) with \( p \) the term denoting the probability of necessity and sufficiency \( P([X = 0] Y = 0 \land [X = 1] Y = 1). \)
handle conditional effects, since, e.g., \( P(\{\alpha|\beta|\gamma\} \geq t) \) can be rewritten as \( P(\{\alpha\}|\beta \land \gamma) \geq t \cdot P(\{\alpha\}) \).\(^1\)

In a companion manuscript (Bareinboim et al. 2020) we improve upon Props. 1 and 2 by showing that for \( i < j \) the \( L_i \)-theory of a model almost-never determines its \( L_j \)-theory, in the sense that the proportion of models where such collapse occurs goes asymptotically to zero.

Graph Definability and Do-Calculus

Given the languages and interpretation considered so far, we mention as an aside that it may be enlightening to consider a notion of graph validity, analogous to “frame validity” in modal logic (van Benthem 2001). Let us say \( G \vdash \varphi \) just in case \( G \models \varphi \) for all Markov structures \( G \) such that \( G = G_{\text{gr}} \).

For any dag \( G \) there is a probability distribution \( P \) whose conditional independencies are exactly those implied by d-separation in \( G \) (Geiger and Pearl 1990). It is then easy to construct an SCM \( G_{\text{gr}} \) with \( G = G_{\text{gr}} \) and \( P = P_{\text{gr}} \), which immediately gives: \(^2\)

**Proposition 3.** \( G \models P(X \land Y | Z) \equiv P(X|Y,Z)P(Y|Z) \) if and only if \((X \perp\perp Y)_{G}\). In other words, the graph property of d-separation is definable in \( L_1 \).

One of the most intriguing components of structural causal reasoning is the do-calculus (Pearl 1995; 2009; Zhang 2008), allowing the derivation of causal effects from observational data. This calculus can also be seen as involving graph validity. The next proposition is a slight extension of what was already proved in (Pearl 1995), combined with the result of (Geiger and Pearl 1990) mentioned above.

**Proposition 4.** Let \( G \) be a dag over variables \( X \).\(^3\) Then (1) \( G \models P(\{X|Y|Z \land W\}) \equiv P(X|Y|Z|W) \) if \((Y \perp\perp Z)_{G} \); (2) \( G \models P(X \land Y|Z|X \land Z|W) \equiv P(X|Y|Z|X \land W) \) if \((Y \perp\perp Z)_{G} \); and (3) \( G \models P(X \land Z|Y \land X \land Z|W) \equiv P(X|Y|Z|W) \) if \((Y \perp\perp Z)_{G} \). All formulas here are in \( L_2 \).

We leave further exploration of questions about graph definability in these languages for a future occasion.

Axiomatizations

We now give systems \( AX_i \) each of which axiomatizes the validities of \( L_i \) over both \( M \) and \( M^* \). These probabilistic logics build on the base (deterministic) logics, as any equivalent base formulas must be assigned the same validity. We call \( \varphi \in L_i^* \) an \( L_i^\text{base} \)-validity, and write \( \models_{L_i^\text{base}} \varphi \), if for all \( F \) and \( u \) we have \( F, u \models \varphi \). For \( \varphi \in L_{i\text{prop}}, \) write \( \models \varphi \) if \( \varphi \) is a propositional tautology. The validities of \( L_3^\text{base} = L_{i\text{all}} \)

---

1In the notation of do-calculus (Pearl 1995; 2009), the expression \( P(\{\alpha|\beta|\gamma\}) \) would be written as \( P(\beta/\{\alpha\}) \).

2\( P(X \land Y | Z) \equiv P(X|Z)P(Y|Z) \) represents a conjunction over all instances of this schema with all combinations of values \( X = x \), \( Y = y \), \( Z = z \). Here \( X, Y, Z \) are lists of variables and \( x, y, z \) are corresponding lists of values in the respective ranges.

3\( G_{X|Z} \) is \( G \) minus any edges into \( X \) or out of \( Z \), and \( Z(W) \) is the set of all \( Z \)-nodes that are not ancestors of any \( W \)-node in \( G_{X|Z} \).

4In (Ibeling and Icard 2019), \( \text{Def} \) merely amounts to the law of excluded middle since \( \text{Val}(X) = \{0, 1\} \) for all \( X \in \mathcal{X} \); here we assume only that every \( \text{Val}(X) \) is finite.
for any specific values \(x^*\) and \(y^*\). (Rather than writing, e.g., \(X = x\), we are simply writing \(x\).) This formula (in \(L_2\)) is not in general valid. But it does follow from further assumptions easily stable in \(L_2\). Formulas (2)-(4) below are instances of the second \(do\)-calculus schema, while (5) and (6) are instances of the third schema (recall Prop. 4).

\[
\begin{align*}
\text{P}([X]Z) & = \text{P}(Z|X) \\
\text{P}([X]Y|[Z]X) & = \text{P}(X \land Z|Y) \\
\text{P}([Z]Y|[X]Z) & = \text{P}(Y|X \land Z) \\
\text{P}(X \land Z|Y) & = \text{P}(Z|X) \land \text{P}(X|Y) \\
\text{P}([Z]X) & = \text{P}(X)
\end{align*}
\]

(Prop. 4) provides the graphical assumptions needed to justify each of these assertions. For example, they are all valid over the graph in Fig. 1 (Pearl 1995; 2009). We now argue that \((2) \land (3) \land (4) \land (5) \land (6)\) \(\rightarrow\) (1) is derivable in our calculus. Notably, this can be done in \(L_2\) using only \(\mathcal{A}_\mathcal{X}\). First, by appeal to MP, Bool, and Dist, we have that \(\text{P}([x^*]y^*) \equiv \text{P}(\bigvee_i ([x^*]y^i \land [x^*]z^i))\), which in turn using Add2 is equal to \(\sum_i \text{P}(x^i|z^i)\text{P}(x^i|y^i|x^i)\text{P}(z^i|x^i)\). By Poly this can be shown equal to \(\sum_i \text{P}(z^i|x^i)\text{P}(x^i|z^i|y^i)\text{P}(x^i|z|x^i)\). By (2) and (3) this is equal to \(\sum_i \text{P}(z^i|x^i)\text{P}(z^i|y^i)\text{P}(z^i|x)\). Employing a similar argument to that above (using MP, Bool, Add2, and Dist), this is equal to \(\sum_i \text{P}(z^i|x^i)\sum_i \text{P}(z^i|y^i|z^i)\text{P}(z^i|x)\). By (4) and (6) we finally obtain \(\sum_i \text{P}(z^i|x^i)\sum_j \text{P}(y^j|x \land z)\text{P}(x)\).

**Completeness Theorems**

**Theorem 5.** Each \(\mathcal{A}_\mathcal{X}\) is sound and complete for the validities of \(L_1\) with respect to both \(\mathcal{M}\) and \(\mathcal{M}^*\).

**Proof.** Soundness is straightforward. For completeness, we show any consistent \(\varphi \in L_1\) is satisfiable. There is a consistent clause in its disjunctive normal form so we may assume that \(\varphi\) is a conjunction of literals (using MP, Bool). We can now obtain a normal form for \(\varphi\) as in (Fagin, Halpern, and Megiddo 1990). Le. 6. Below gives us the \(i = 1, 3\) case. We will show later how to modify it (Lem. 9) for \(\mathcal{A}_\mathcal{X}\).

**Lemma 6.** Suppose \(\varphi \in L_1\) is a conjunction of literals. Let \(a_1, \ldots, a_n \in L_1^{\text{base}}\) be the base atoms appearing in \(\varphi\). Let \(\Delta = \{\ell_1 \land \cdots \land \ell_n : \ell_i \in \{a_i, \neg a_i\}\} \text{ for all } 1 \leq i \leq n\). Let \(\Delta_{\perp} = \{\delta : |\ell_\varphi| \land \delta \Downarrow \perp\}\). Then there are polynomial terms \(t_1, \ldots, t_m, t_1', \ldots, t_m',\) in the variables \(\{\mathcal{P}(\delta)\}_{\delta \in \Delta}\) such that \(\varphi\) is provably-in-\(\mathcal{A}_\mathcal{X}\) equivalent to a conjunction

\[
\begin{align*}
\bigwedge_{\delta \in \Delta_{\perp}} \mathcal{P}(\delta) & \equiv 0 \land \bigwedge_{\delta \in \Delta \setminus \Delta_{\perp}} \mathcal{P}(\delta) \geq 0 \land \sum_{\delta \in \Delta} \mathcal{P}(\delta) & \equiv 1 \\
\bigwedge_{1 \leq i \leq m} t_i & \equiv 0 \land \bigwedge_{1 \leq i \leq m'} t_i' & \equiv 0.
\end{align*}
\]

(7)

**Proof.** The first part of (7) comes from Dist, the second from NonNeg, and the remainder from Add and Poly. This is most clearly illustrated by Example. Consider \(\varphi = \mathcal{P}([X]Y) + 2\mathcal{P}([Y]Z) \equiv 1/2\) so that \(\Delta = \{\delta_1 = [X]Y \land [Y]Z, \delta_2 = [X]Y \land \neg[Y]Z, \delta_3 = \neg[X]Y \land [Y]Z, \delta_4 = \neg[X]Y \land \neg[Y]Z\}\) and \(\Delta_{\perp} = \emptyset\). Let \(p\) abbreviate \(\mathcal{P}(\delta_1)\). By NonNeg, \(\vdash (p_1 \geq 0) \land \cdots \land (p_4 \geq 0)\) and by Add, \(\vdash p_1 + \cdots + p_4 \equiv 1\). Now, we may compute the \(t_i, t'_i\) in (1). Using Poly and Add:

\[
\begin{align*}
\vdash \varphi & \equiv 2\mathcal{P}([X]Y) + 4\mathcal{P}([Y]Z) - 1 \equiv 0 \\
\vdash \varphi & \equiv 2\mathcal{P}([X]Y) \land \neg[Y]Z + 2\mathcal{P}([X]Y) \land [Y]Z) + 4\mathcal{P}([X]Y) \land [Y]Z + 4\mathcal{P}([X]Y) \land \neg[Y]Z) - 1 \equiv 0 \\
\vdash \varphi & \equiv \neg p_1 + 2p_2 + 4p_3 \equiv 0 \\
\vdash \varphi & \equiv \neg p_1 + 2p_2 + 4p_3 \equiv 0 \\
\neg \vdash \neg p_1 - 4p_2 - 4p_3 \equiv 0
\end{align*}
\]

so that \(m = 2, m' = 0\) in (7), and \(t_1 = \neg p_1 + 2p_2 + 4p_3 \equiv 0\) while \(t_2 = -t_1\). We can carry out this process for any \(\varphi\), with \(m' \neq 0\) if \(\varphi\) contains negations.

(7) is a system of polynomial inequalities in the unknowns \(\{\mathcal{P}(\delta)\}_{\delta \in \Delta}\). We now demonstrate this system has a solution provided (7) is consistent. Our primary tool is the following semialgebraic result (Stengle 1974).

**Theorem 7** (Positivstellensatz). Let \(R = \mathbb{Q}[x_1, \ldots, x_n]\) and suppose \(f_1, \ldots, f_s, g_1, \ldots, g_t, h_1, \ldots, h_m \in R\). Let \(\text{cone}(g_1, \ldots, g_t) \subseteq R\) be the closure of \(\{g_1, \ldots, g_t\} \cup \{s^2 : s \in R\}\) under addition and multiplication, and let \(\text{ideal}(h_1, \ldots, h_m) = \{\sum_{i=1}^m a_i h_i : a_i : a_m \in R\}\). Then either the system \(\{f_i \neq 0, g_j \geq 0, h_k = 0 : 1 \leq i \leq s, 1 \leq j \leq t, 1 \leq k \leq m\}\) has a solution over \(\mathbb{R}^n\), or there exist \(g \in \text{cone}(g_1, \ldots, g_t), h \in \text{ideal}(h_1, \ldots, h_m), n \in \mathbb{N}\) with

\[
g + h + F^{2n} = 0
\]

where \(F = \prod_{1 \leq i \leq s} f_i\).

Each clause in (7) easily translates to a polynomial in Thm. 7; a clause \(t_i' > 0\) becomes two constraints: \(t_i' \geq 0\) and \(t_i' \neq 0\). If there’s no solution, let \(t = (g + h) + F^{2n}\) for some \(g, h, f\) as in (8), where \(F^{2n}\) is an iterated multiplication. We claim \(\varphi \vdash \exists t \equiv 0 \land t > 0\) so that \(\varphi\) is inconsistent, a contradiction. We use the principles below, all derivable from Poly:

\[
\begin{align*}
\text{AddPos.} & \quad t_1 > 0 \land t_2 > 0 \rightarrow t_1 + t_2 > 0 \\
\text{MulPos.} & \quad t_1 > 0 \land t_2 > 0 \rightarrow t_1 \cdot t_2 > 0 \\
\text{NegAdd.} & \quad -(t_1 + t_2) \equiv (-t_1) + (-t_2) \\
\text{NegNeg.} & \quad -(-t) \equiv t \\
\text{OrdSq.} & \quad t \cdot t \equiv 0
\end{align*}
\]
First, we show \( \varphi \vdash t > 0 \). Note that \( \varphi \vdash g \geq 0 \) by OrdSq and \( \varphi \vdash h \equiv 0 \) by ZeroMul given Thm. 7 and the clauses of (7). Also, \( \varphi \vdash f > 0 \) by NonDegen if \( m' = 0 \) in (7) or \( n = 0 \) in (8) and by MulPos otherwise. So \( \varphi \vdash (g + h) + 2n > 0 \) by AddPos. Now we show \( \varphi \vdash t = 0 \). In fact, we don’t need \( \varphi \). We show that Poly is powerful enough to simplify polynomials; then by soundness and since (8) holds identically, \( t = 0 \). Using MulDist, NegAdd, \( \vdash t = m \) where \( m \) is a sum of non-\( \varphi \) monomials, each of which is either \( 1 \) itself or contains no factors of \( 1 \) (One), and contains at most one \( \sim \) sign (NegNeg). By MulComm, MulAssoc group the factors in each left-associatively and in increasing (lexicographic) order of their variables. Then with AddComm, AddAssoc, Neg group and cancel out to \( 0 \) equal but opposite monomials. Adding all the \( 0 \)'s, we have \( \vdash m = 0 \).

The \( \{\{\varphi]\}_\delta \) can be assumed computable, as there is an algebraic (Tarski 1949) and a fortiori computable solution to (7). Now, this implies there is a \( M \in M^* \subset M \) that satisfies each \( \delta \in M \setminus L \Delta \), with probability \( P(\delta) \), so that \( M \models \varphi \).

**Lemma 8.** Let \( \{\varphi_i\}_{1 \leq i \leq N} \) be satisfiable \( L_{\text{full}} \)-formulas with no pair of which is jointly satisfiable, and let \( \{p_i\}_{1 \leq i \leq N} \) be noncomputable reals summing to unity. Then there is a \( M \in M^* \) such that \( P(\varphi_i|n) \equiv p_i \) for all \( 1 \leq i \leq N \).

**Proof.** (Ibeling and Icard 2019) give semantics of \( L_{\text{full}} \) over deterministic SCMs, i.e., those in which \( \mathcal{U} = \emptyset \). Thus there are deterministic \( M_i = \{\{f_i\}_{x \in X_i}\} \) such that \( M_i \models \varphi_i \) for all \( i \). Consider \( M = (\mathcal{F}, \mathcal{P}) \) with \( \mathcal{U} = \{U\} \) such that \( \mathcal{V}(U) = \{1, \ldots, N\} \), where for all \( i \) the probability that \( U = i \) is \( P_i \). Define \( \mathcal{F} = \{f_i\}_{x \in X_i} \) as \( f_i(g) = f_i(x) \) for any endogenous setting \( g \). When \( U = i \), the structural equations of \( M \) and \( M_i \) coincide, so \( \mathcal{F}, i \models \varphi_i \). Conversely, if \( \mathcal{F}, i \models \varphi_j \), then \( j = i \); otherwise \( M_i \models \varphi_i \land \varphi_j \). Thus \( S_{\text{mn}}(\varphi_i) = \{i\} \) and \( P(\varphi_i|\text{mn}) = p_i \) for all \( i \). Clearly \( M \) can be made to satisfy Def. 3.

As for the \( \text{AX}_2 \) case, Lem. 6 must be modified, but the proof is the same (no elements of \( \Delta \) are jointly satisfiable):

**Lemma 9.** Suppose \( \varphi \in L_2 \) is a conjunction of literals. Let \( \alpha_1, \ldots, \alpha_n \in L_{\text{prop}} \) be the \( \text{prop} \)-atoms appearing in \( \varphi \) (i.e., its subformulas of the form \( X = \alpha \)) and let \( \alpha_1, \ldots, \alpha_n \in L_{\text{int}} \) be the antecedents of any conditionals appearing in \( \varphi \). Let \( \Delta_{\text{prop}} = \{\ell_1 \wedge \cdots \wedge \ell_n : \ell_i \in \{\alpha_i \land \neg \alpha_i\} \text{ for all } 1 \leq i \leq n\} \) and let \( \Delta = \{(\alpha_i)_{\delta_{\text{prop}} : 1 \leq i \leq \ell, \delta_{\text{prop}} \in \Delta_{\text{prop}})} \). Let \( \Delta_{\perp} = \{\delta : \neg \alpha \in \Delta_{\text{prop}}\} \). Then there are polynomial terms \( t_1, \ldots, t_m, t'_1, \ldots, t'_m \) in the variables \( \{\varphi\}_{\delta \in \Delta_{\perp}} \) such that \( \varphi \) is provably-in-\( \text{AX}_2 \) equivalent to a conjunction

\[
\bigwedge_{\delta \in \Delta_{\perp}} P(\delta) = 0 \land \bigwedge_{\delta \in \Delta \setminus \Delta_{\perp}} P(\delta) = 0 \land \\
\bigwedge_{1 \leq i \leq \ell} \sum_{\delta_{\text{prop}} \in \Delta_{\text{prop}}} P(\alpha_i)_{\delta_{\text{prop}}} = 1 \land \\
\bigwedge_{1 \leq i \leq m} t_i \leq 0 \land \bigwedge_{1 \leq i \leq m'} t'_i > 0.
\]

**Proof.** Use Add2 in place of Add in proving Lem. 6.

**Complexity**

Let \( \text{PROB-CAUSAL-SAT}_i \) be the problem of deciding if a given formula \( \varphi \in L_i \), encoded standardly, is satisfiable. The completeness proof above delivers no obvious complexity bound, but we will now obtain a polynomial space bound by extending an argument of (Fagin, Halpern, and Megiddo 1990). As PSPACE closes under complement, this also shows the validity problem for our languages is in PSPACE. The crux is a small-model property:

**Lemma 10.** Any satisfiable \( \varphi \) has a small model \( M \) in the sense that \( \{\delta \models \varphi : |M| > 0\} \leq |\varphi| \) where \( \varphi \) is defined as in Lem. 6, 9.

**Proof.** Let \( \Psi \) be the \( L_{\text{new}} \)-formulas appearing inside \( \varphi \); we have \( |\Psi| < |\varphi| \). For \( \varphi \in \Psi \) let \( \Delta_{\psi} = \{\delta : \models \psi \models \psi\} \); the proof of Lem. 6 or 9 show that \( \sum_{\delta \in \Delta_{\psi}} P(\delta) = P(\psi) \) is valid. Now let \( \Delta' \) be such that \( \Delta' \models \varphi \) and consider the system \( S \) in the unknowns \( \{\{P(\delta)\}_{\delta \in \Delta} : S = \sum_{\delta \in \Delta} P(\delta) = 1 \} \cup \sum_{\delta \in \Delta_{\psi}} P(\delta) : \psi \in \gamma \). By a fact of linear algebra (Fagin, Halpern, and Megiddo 1990, Lem. 2.5), since \( S \) has \( |\Psi| + 1 \) equations, it has a nonnegative solution \( s \) where at most \( |\Psi| + 1 \) variables are nonzero. Apply Lem. 8 to \( s \), giving a small \( M \) such that \( \models \varphi \models \varphi \) for all \( \psi \in \Psi \), so that \( M \models \varphi \).

**Theorem 11.** Each \( \text{PROB-CAUSAL-SAT}_i \in \text{PSPACE} \).

**Proof.** Algorithm: for each subset \( \Delta' \subseteq \Delta \) of size \( |\Delta'| \leq |\varphi| \), form a formula \( \varphi_{\Delta'} \) in the existential theory of the reals \( (\mathbb{R}) \), over variables \( \{p_\delta\}_{\delta \in \Delta'} \) as follows. Conjoin the equations \( \sum_{\delta \in \Delta} p_\delta = 1 \) and \( \sum_{\delta \in \Delta} p_\delta \geq 0 \) to the result of replacing any \( P(\psi) \) appearing in \( \varphi \) with \( \sum_{\delta \in \Delta} p_\delta \). Then check satisfiability of \( \varphi_{\Delta'} \) via the PSPACE decision procedure for \( (\mathbb{R}) \) of (Canny 1988). Declare \( \varphi \) satisfiable if any \( \varphi_{\Delta'} \) is satisfiable, and unsatisfiable if not. Why does it work? \( \varphi \) is satisfiable, we have a model with a small \( \Delta' \) by Lem. 10, and the corresponding \( \{p_\delta\}_{\delta \in \Delta'} \) are a witness for \( \varphi_{\Delta'} \). Conversely, if \( \varphi_{\Delta'} \) is satisfiable in \( \mathbb{R} \) for some \( \Delta' \), then apply Lem. 8 to the reals \( \{p_\delta\}_{\delta \in \Delta'} \), giving a model satisfying \( \varphi \).

**Probabilistic Programs**

Thm. 5 establishes soundness and completeness for both the class of measurable SCMs, and also for the more restricted class of computable SCMs. The latter result is especially useful for establishing a link to an alternative perspective on causal modeling, emphasizing a procedural rather than declarative aspect (Icard 2017). We take a probabilistic program to be any generative algorithm:

**Definition 4** (Probabilistic simulation model). A probabilistic simulation model \( \text{Sim} \) is a probabilistic Turing machine with a read-only random bit tape, a work tape, and a write-only variable tape encoding the variables \( X \).

A probabilistic simulation outputs values for endogenous variables, eventually establishing a complete endogenous setting \( \mathbf{r} \) on the variable tape. Thus, like a SCM, a probabilistic simulation model \( \text{Sim} \) gives a probability distribution \( \mathbf{P}(X) \). The following definition of intervention endows these models with a genuine causal interpretation:
Definition 5. Given a computable intervention \( i \) (as in Def. 2) and a corresponding oracle \( i \) that emulates \( T \) but acts as if the square for any \( X \in i \) is fixed to the value \( i(X) \); it dovetails this emulation with a procedure that writes \( i(X) \) for all \( X \in \text{dom}(i) \).

In (Ibeling and Icard 2019) a subclass \( T^* \) of simulation programs is studied, namely those (1) that satisfy a strong “functionality” property for interventions, (2) that produce a solution under every intervention, and (3) for which the direct causal influence relation is well-founded (analogously to the requirement above for SCMs). We can then obtain:

Theorem 12. For every \( \mathcal{M}^* \in \mathcal{M}^* \) there is a \( T \in T^* \) such that, for every computable intervention \( i \), we have \( P_i(\mathcal{M}^*) = \mathcal{P}_i(T^*) \), and vice versa.

Proof. The only difference between the present setting and the one in (Ibeling and Icard 2019) is the presence of an infinite sequence of random bits (recall Def. 3 for SCMs). Thus, the same construction as in (Ibeling and Icard 2019, Thm. 1) gives a model for which, when a random bit string is fixed, we have equivalence under any interventions of the endogenous variables.

With the obvious interpretation of \( L_1 \) formulas over simulation models in \( T^* \), we thus have:

Corollary 13. Each \( AX_i \) is sound and complete for the validities of \( L_1 \) with respect to \( T^* \).

Conclusion

We have introduced a series of increasingly expressive languages encoding levels of the “ladder of causation” (Shpitser and Pearl 2008; Pearl 2009), interpreted over both standard structural causal models and probabilistic simulation programs. We moreover established some fundamental theoretical results about these languages, including finitary axiomatizations and \( \text{PSPACE} \) complexity upper bounds for satisfiability and validity. This marks the first systematic study of a probabilistic logic of causal counterfactuals.

Along the way we also noted how logical languages might help to illuminate aspects of probabilistic causal reasoning. As a final illustration, let us return again to the \( \text{do} \)-calculus. We noted two seminal formula schemas from \( L_2 \) that feature centrally in the \( \text{do} \)-calculus:

\[
\begin{align*}
P((X \land Z)Y | X \land ZW) & \equiv P((X Y | X)(Z \land W)) \quad (10) \\
P((X \land Z)Y | X \land ZW) & \equiv P((X Y | X)W) \quad (11)
\end{align*}
\]

Where \( \Gamma \) is a set of \( L_3 \) formulas, let \( \Gamma_{\text{do}} \) be all instances of (10) and (11) that can be inferred from \( \Gamma \) using the rules and axioms of \( AX_3 \) (equiv. are entailed by \( \Gamma \)). As usual, we say \( \Gamma \vdash \varphi \) to mean that \( \Gamma \) semantically entails \( \varphi \), while \( \Gamma \vdash \varphi \) means there is a proof in \( AX_3 \) of \( \varphi \) from assumptions in \( \Gamma \). The completeness results of (Huang and Valtorta 2006; Shpitser and Pearl 2008), together with Thm. 5, establish the following combined completeness result:

Corollary 14. Let \( p \) be a term of \( L_1 \) and \( \chi \in L_2^\text{base} = L_{\text{cond}} \). Then \( \Gamma \vdash P(\chi) \equiv p \) implies \( \Gamma_{\text{do}} \vdash P(\chi) \equiv p \).

In other words, to know whether a causal effect \( P(\chi) \) can be reduced to a pure probabilistic expression \( p \), given some set of assumptions \( \Gamma \), it suffices to take as premises only instances of (10) and (11) (which by Prop. 4 can all be inferred from specific graphical properties), and apply the calculus \( AX_3 \) (or simply \( AX_2 \)). The derivation of (1) from (2)-(6) above is a concrete illustration of this Corollary.

More generally, we submit that the formalization of causal languages offered in this paper helps to clarify what exactly the levels of the causal hierarchy come to, and how we might gain a better understanding of how they relate to each other and to tasks that an intelligent agent might need to solve. For a start on such exploration, see (Bareinboim et al. 2020).

Future Work

Our work opens up a number of possibilities for further investigation. We mention several here.

Although the complexity of decision problems for the languages considered here is relatively low compared to many expressive logical systems, it may be desirable to consider yet smaller fragments of probability logic. For example, the language of probability statements with linear inequalities remains in \( \text{NP} \) (Fagin, Halpern, and Megiddo 1990). While this fragment is too impoverished to express general assertions about conditional probability, one could extend the language only minimally: cf. (Ivanovska and Giese 2010).

It is also natural to consider more expressive languages. For instance, (Ibeling and Icard 2019) included a (deterministic) causal influence relation \( \sim \) explicitly in the logical language, showing, e.g., that transitivity of this relation characterizes exactly the “local” SCMs (Pearl 2009). Would this characterization extend to the probabilistic interpretation of causal influence? Indeed, from the perspective of causal learning and reasoning it would be natural to include explicit statements about the underlying graph in the logical syntax (Geiger and Pearl 1990; Hyttinen, Eberhardt, and Järvisalo 2014; 2015; Triantafillou and Tsamardinos 2015).

On the other hand, leaving graph properties merely implicit as we have done here raises numerous theoretical questions about graph definability, as briefly explored above. Analogous to the case of modal logic, we can ask for the class of graphical properties that can be defined by \( L_1 \), \( L_2 \), or \( L_3 \). Considering different types of causal graphs may lead to variations of this question, e.g., with mixed ancestral graphs (Spirtes, Glymour, and Scheines 2000) which we know reveal a different version of Prop. 4 (Zhang 2008).

Finally, while Props. 1 and 2 report known results establishing basic strictness of the hierarchy, it would of course be desirable to develop a much more comprehensive and systematic theory of expressiveness for the three languages, again akin to what we have for many other logical languages. What kinds of invariance properties do these languages imply? We leave these open questions for future work.
