Surface changes in the North Atlantic meridional overturning circulation during the last millennium

Despite numerous investigations, the dynamical origins of the Medieval Climate Anomaly and the Little Ice Age remain uncertain. A major unresolved issue relating to internal climate dynamics is the mode and tempo of Atlantic meridional overturning circulation variability, and the significance of decadal-to-centennial scale changes in Atlantic meridional overturning circulation strength in regulating the climate of the last millennium. Here we use the time-constrained high-resolution local radiocarbon reservoir age offset derived from an absolutely dated annually resolved shell chronology spanning the past 1,350 years, to reconstruct changes in surface ocean circulation and climate. The water mass tracer data presented here from the North Icelandic shelf, combined with previously published data from the Arctic and subtropical Atlantic, show that surface Atlantic meridional overturning circulation dynamics likely amplified the relatively warm conditions during the Medieval Climate Anomaly and the relatively cool conditions during the Little Ice Age within the North Atlantic sector.
Palaeoclimate records from sediments beneath the Florida Current indicate that the Gulf Stream transport decreased by ~10% during the Little Ice Age (LIA). It has been suggested that this decreased meridional heat transport by the Gulf Stream and the North Atlantic Current (NAC) may have been partly responsible for LIA cooling. Instrumental series of Gulf Stream/NAC and Atlantic meridional overturning circulation (AMOC) behaviour and heat transports are limited to a few decades. This lack of long instrumental records, information about ocean variability in the North Atlantic on longer timescales can only be obtained from geological proxy archives.

To better understand the physical causes of the Medieval Climate Anomaly (MCA) and LIA climate intervals, additional high-quality palaeodata, from diverse geographic settings, including the global oceans, are required to confidently document the spatial and temporal scope of the MCA and LIA. Although the dynamical origins of the MCA and LIA have been widely studied, many aspects of these climate intervals are still poorly characterized and widely debated. Key candidate forcings include external climate drivers (for example, volcanic and solar activity) and internal Earth system feedbacks. Beyond external climate forcings, it is recognized that natural variability in heat transport via the Gulf Stream and the NAC (which together make up the northward-flowing surface component of the AMOC) to higher latitudes within the Atlantic basin was likely influential in shaping the MCA and LIA climate events. However, this hypothesis has been difficult to test because of a scarcity of suitable precisely dated natural marine proxy archives located within the region of influence of the AMOC.

To reconstruct the dynamics of Arctic and Atlantic water masses in this region over the last millennium, we analysed the radiocarbon data in a format that reflects oceanic mixing processes (upwelling, advection) in the vicinity of the oceanic Polar Front. NAC waters (ΔR values = 0 to 50) flow northward and clockwise around West Iceland as the Irminger Current and mix on the North Icelandic shelf with Arctic water (ΔR values >150), flowing southeastward as the East Icelandic Current (a periodic development of the East Greenland Current; Fig. 1). Our findings indicate a declining influence of NAC waters on the North Icelandic shelf during the last millennium. Since circa AD 1940, NAC-derived surface waters have again become more influential north of Iceland and within the Arctic, resembling hydrographic conditions present during the early MCA. We infer that the surface AMOC was relatively strong in Medieval times, became weaker in the LIA, and strengthened again after circa AD 1940. We suggest that the surface component of the AMOC amplified the relatively warm conditions during the MCA and the relatively cool conditions during the LIA within the North Atlantic Ocean.

Figure 1 | Location map of modern ocean surface circulation patterns in the northern North Atlantic. The A. islandica study site on the North Icelandic shelf is shown with a star; map modified from ref. 25.
To determine the likely population-wide common environmental signal. By convention, (1−Rbar)) to give an indication of the degree to which the population

Expressed Population Signal (EPS; red line in Figure 2) indicating relatively older waters on the North Icelandic shelf; these data are most consistent with a water mass of Arctic origins. This apparent trend (increasing marine radiocarbon reservoir effect) continues into the LIA, until it is briefly interrupted by an atmospheric 14C pulse from AD 1375 to AD 1400, which is clearly seen in the Marine09 record and the 14C shell data (highlighted as Case #3 in Figure 4). At least one other atmospheric 14C perturbation is noted in the shell-based 14C at ~AD 1790 (highlighted as Case #4 in Figure 4). During the entirety of the LIA climate interval, waters along the North Icelandic shelf are older than the global ocean. For the first time since the early MCA, shell-based 14C values equal the global ocean values at AD 1895 and AD 1950, likely indicating a shift to Atlantic-derived waters. Although decadal trends in

(b) Detrended growth increments normalized as z-scores ((value − mean)/standard deviation) derived from the autoregressive modelled chronology with a 70-year low pass centrally weighted Gaussian filter; see ref. 27 for additional details. (c) Expressed population signal (EPS; red) with the 0.85 critical value noted, and the mean correlation between all detrended series (Rbar; blue). (d) Mean longevity of all shells in the chronology at that point. (e) Sample depth of chronology at that point.

Results

Master shell chronology. A total of 29 shells (14 dead-collected and 15 live-collected) were used to construct the master shell chronology27. The shell chronology27 extends 1,357 years, and represents the longest continuous annually resolved sclerochronological record (Fig. 2). The mean correlation between all detrended series (Rbar; blue line in Fig. 2c)24 is defined only after circa AD 1200, because, before then, sample depth does not exceed two at any point (Fig. 2e). The value of Rbar (determined in a 50-year window at 25-year intervals) is low around AD 1200, probably because a prevalence of juvenile specimens in the chronology at that point introduces greater ontogenetic variability. It also falls slightly around AD 1450–1500 and in the late 1700s, indicating a weaker common signal. The Expressed Population Signal (EPS; red line in Fig. 2c)25 takes account of both Rbar and the sample depth N (EPS = N×Rbar/(N×Rbar+ (1−Rbar))) to give an indication of the degree to which the population subsample, included in the chronology, expresses the theoretical population-wide common environmental signal. By convention, EPS ≥0.85 is taken to indicate that the expression of the common signal is adequate25. Here the EPS falls below 0.85 only at the start of the period for which it is defined (circa AD 1200) and during the period AD 1450–1500, when the common signal is relatively weak. It is also notable that EPS does not increase significantly during the twentieth century when the inclusion of a number of live-collected specimens in the chronology raises the sample depth to 15. This indicates that for increment width series that correlate as closely as these, a sample depth between four and six is normally sufficient to provide an adequate signal to noise ratio. The longevity of the animals used here, determined by increment counting and cross-dating, ranks them among the longest lived non-colonial animals known to science. Of particular note are shells 061294 and 061364, which lived for 507 years and 412 years, respectively27. These two animals seem to have settled on the sea floor north of Iceland at about the same time (circa AD 1500), and the raw increment widths from their shells correlate strongly (r = 0.89; P < 0.0001) through a period of 410 years (Fig. 3).

Origin of radiocarbon signal in shells. To determine the likely origin of the radiocarbon signal (atmospheric versus oceanic) in the cross-dated shells, we compared the shell 14C data with the radiocarbon record for the atmosphere (IntCal09)28 and the modelled global ocean (Marine09)28 (Fig. 4). During this interval (AD 600 to AD 1950), the modelled global ocean28 on average 386 (±39) years older than the atmosphere with respect to radiocarbon (Fig. 4; see also ref. 29, for a detailed discussion). Further, changes in the global ocean 14C record are slightly lagged and attenuated compared with the atmosphere. In the early part of the record (AD 675 to AD 705 and AD 870 to AD 940) (highlighted as Case #1 in Fig. 4), the shell-derived 14C values match the global ocean values. This indicates that a water mass of Atlantic origins (for example, NAC, a water mass that is about 400-years old with respect to radiocarbon) was prevalent on the North Icelandic shelf during the early MCA. Conversely, from AD 1000 to AD 1210, there was a clear departure in shell 14C values from the global ocean (highlighted as Case #2 in Fig. 4) indicating relatively older waters on the North Icelandic shelf; these data are most consistent with a water mass of Arctic origins24. This apparent trend (increasing marine radiocarbon reservoir effect) continues into the LIA, until it is briefly interrupted by an atmospheric 14C pulse from AD 1375 to AD 1400, which is clearly seen in the Marine09 record and the 14C shell data (highlighted as Case #3 in Fig. 4). At least one other atmospheric 14C perturbation is noted in the shell-based 14C at ~AD 1790 (highlighted as Case #4 in Fig. 4). During the entirety of the LIA climate interval, waters along the North Icelandic shelf are older than the global ocean. For the first time since the early MCA, shell-based 14C values equal the global ocean values at AD 1895 and AD 1950, likely indicating a shift to Atlantic-derived waters. Although decadal trends in
atmospheric $^{14}$C dynamics are faithfully recorded in the shell record (Fig. 4), the increasing deviation between the Marine09 record and the shell-based radiocarbon signal north of Iceland cannot be explained by atmospheric forcing.

Changes in $\Delta R$ data during the last millennium. We present 41 new $\Delta R_{\text{shell}}$ data (orange circles) spanning AD 675 to AD 1950; the subsamples necessarily integrate several annual increments, so some measurements have a temporal integration of 5 to 20 years (Fig. 5; Supplementary Data 1). The $\Delta R_{\text{shell}}$ values gradually increase over the last millennium, reflecting a shift towards older Arctic-derived water. Decadal- to multi-decadal scale variations in $\Delta R_{\text{shell}}$ values are most pronounced in the early part of the record and since circa AD 1800. Comparison with known present-day measurements of $\Delta R$ (ref. 36) indicates that $\Delta R_{\text{shell}}$ values before and during the early MCA (for example, AD 675-AD 1000) mostly reflect waters derived from an Atlantic (NAC) source, whereas during much of the MCA (after AD 1000) and into the early LIA$^{24}$ they indicate a varying mixture of Atlantic and Arctic sources. Progressing into the LIA (after AD 1500), the $\Delta R_{\text{shell}}$ values are most consistent with a dominant Arctic (East Icelandic Current) source. In AD 1915, the highest $\Delta R_{\text{shell}}$ value ($\Delta R = 200$) is reached. After AD 1915, there is an apparent reversal in $\Delta R_{\text{shell}}$ values.

Comparison of $\Delta R$ data with other AMOC-sensitive proxy records. To establish a more comprehensive reconstruction of $\Delta R$ variability along the North Icelandic shelf, we compare our results with sediment-based $\Delta R$ values from two high-resolution records$^{24}$ (squares) collected from the vicinity of the shell location, but at 440 m (core MD99-2275) and 665 m (core MD99-2273) water depths, respectively (Fig. 5). Because of the positions of these sediment archives, numerous Holocene tephras from Icelandic volcanic sources$^{37}$ are available to constrain their age/depth relationship$^{24}$ (bottom Fig. 5). These records indicate an increase in $\Delta R$ values during the last millennium (Fig. 5) consistent with the shell values, but a depth-dependendent relationship with $\Delta R$ is also apparent. The relationship between water depth and $\Delta R$ can be explained by the greater contribution of relatively depleted $^{14}$C water that penetrates onto the shelf at greater depths$^{24}$. All three records show a long-term trend to increasing $\Delta R$ values before circa AD 1880, reflecting reduced influence of NAC-derived waters. However, the $\Delta R$ data show a large degree of variability after AD 1880, likely indicating increased variability of oceanographic conditions on the North Icelandic shelf. After circa AD 1940, $\Delta R$ decreases rapidly towards levels characteristic of the early MCA, suggesting a renewed influence of Atlantic sourced waters on the North Icelandic shelf.

Role of upwelling on the $\Delta R$ record. Although regional upwelling can complicate the interpretation of $\Delta R$, the lack of any covariance ($r^2 = 0.01$) between co-registered shell carbon isotope ($\delta^{13}$C) and $^{14}$C measurements (converted to $\Delta R$ values) (Fig. 6; Supplementary Data 1), both of which are sensitive proxies of upwelling$^{38}$, strongly indicates that upwelling is not a control on the Icelandic $\Delta R$ values.

Discussion

Even though we are arguing that the long-term trend in $\Delta R_{\text{shell}}$ values reflects water mass variability, it is possible to make an alternative...
case that it results from atmospheric $^{14}$C dynamics. By definition, regional $\Delta R$ values are derived by subtracting the modelled global ocean $^{14}$C value from the measured $^{14}$C-shell value for a given calendar year (in this case, the sclerochronologically determined year) as noted above$^{30}$. The global ocean $^{14}$C value is determined by modelling the atmospheric $^{14}$C record (INTCAL09; see ref. 28), which is based on the $^{14}$C content of cross-dated tree-ring records. The model used to assign global ocean $^{14}$C values is based on a simple gas exchange model (for more details see ref. 30). As defined by ref. 30, the $\Delta R$ value is composed of two terms: the portion of the shift in regional marine $^{14}$C age attributable to a regional atmosphere $^{14}$C age difference, and an additional shift in marine regional $^{14}$C age, which reflects oceanic processes (such as upwelling and/or advection) that differ from the parameters in the simulated global ocean. Although rapid, decadal-scale atmospheric perturbations in $^{14}$C production seem to impact the $\Delta R$ record (Fig. 4, Cases #3 and #4), gradual and largely unidirectional changes in $^{14}$C activity in the atmosphere (as noted in INTCAL09 for this interval AD 650 to AD 1950; Fig. 4) will not impact the $\Delta R$ values, because these changes are also embedded in the Marine09 model, albeit with a slight lag. Because the $^{14}$C Marine09 data are a smoothed version (with appropriate lag times) of the $^{14}$C atmospheric data (for example, INTCAL09), the increasing deviation in $\Delta R$ during the last millennium at the study site must be of oceanic origin. Hence, we argue that the $\Delta R$ values north of Iceland primarily reflect processes indicative of large-scale ocean circulation dynamics.

The proxy transport estimates from the Florida Straits$^1$ capture a large portion of the northward flow of the Gulf Stream/NAC system (Fig. 5). Comparison of these data with the $\Delta R$ values from the North Icelandic shelf suggests that the latter are coupled to Gulf Stream/NAC discharge and the wind-driven (surface) component of AMOC. The associated distinct and converging water masses (Atlantic and Arctic) associated with the oceanic Polar Front (Fig. 1) are largely driven by regional wintertime mean sea-level pressure gradients$^{59}$ and wind-stress curl over the region$^{10}$. Hence, changes in regional and basin-scale surface wind patterns, such as the North Atlantic Oscillation (NAO), will in part modulate the flux of Atlantic waters flowing northward to Iceland via the Irminger Current$^{40}$.

Over the last millennium, the winter NAO system has been variable, with a strongly positive NAO mode during Medieval times and a neutral to slightly negative NAO mode during the LIA$^{14}$. Over recent decades, the NAO system has been in strong positive mode, similar to the MCA$^{14}$. We hypothesize that the variability in surface AMOC and $\Delta R$ values north of Iceland are in part driven by the mean state of the NAO system during the last 1,000 years (Fig. 7). The northerly position of the Gulf Stream wall, Gulf Stream transport, and surface AMOC dynamics are positively correlated with winter NAO values$^{41,42}$. Additionally, model results link a strengthened AMOC with a northward shift of the path of the Gulf Stream$^{43}$. Under such conditions, a relatively enhanced transport of Atlantic water is carried northwards as the NAC, ultimately decreasing $\Delta R$ values north of Iceland. We infer that the surface component of the AMOC was relatively strong in early Medieval times, became weaker in the LIA, and stronger again after AD ~1940. This inference is corroborated by recent summer sea surface temperature (SST) proxy-based estimates from within the Arctic Ocean$^{10}$ (Fram Strait off western Svalbard; 79°N), a region that is also sensitive to surface AMOC dynamics. The Fram Strait SST data$^{10}$ indicate that the influx of Atlantic water entering the Arctic Ocean has substantially increased in the last 100 to 200 years (Fig. 5), likely causing a significant portion of the modern Arctic warming$^{10}$. Additionally, the relative strength of Atlantic inflow (and associated heat transport) to Fram Strait was apparently high during the MCA and low during the LIA$^{10}$ (Fig. 5). The long-term covariance between Gulf Stream transport estimates and the relative influence of Atlantic and Arctic waters on the North Icelandic shelf (Fig. 5) support the conclusion that the surface strength of the AMOC primarily controls $\Delta R$ values north of Iceland. Additionally, sediment-based SST data$^{24,26}$ from the North Icelandic shelf and Fram Strait$^{10}$ indicate a relatively warm MCA and cold LIA synchronous with the $\Delta R$ data and the evolution of Gulf Stream transport. Although certain mechanistic and dynamical models link aspects of AMOC behaviour to winter NAO forcing$^{43}$, considerable uncertainty remains regarding the physical mechanisms driving this variability at the decadal- to centennial-scale$^{46}$. The current lack of adequately resolved and well-distributed marine proxy data for the strength of AMOC over the last millennium prevents a rigorous testing of the main factors that modulate surface AMOC variability. Additional work is required to establish the boundary conditions and possible mechanisms (for example, increased volcanism in the thirteenth century$^{20}$ and changing Arctic sea ice conditions$^{47,48}$) that led to the inferred surface AMOC weakening and general cooling trend into the LIA climate interval. Despite some progress noted here in documenting the past behaviour of the surface AMOC variability, this study does not reveal any information regarding deepwater formation (rates or volumes) related to AMOC in the northern North Atlantic during this interval. Hence, our understanding of links between the overturning circulation (specifically deepwater formation) and North Atlantic climate, during the last millennium, remains incomplete. The acquisition of high-resolution marine proxy data from regions sensitive to AMOC changes (both surface and deepwater processes) is therefore a major research priority.

Figure 6 | Relationship between shell-stable carbon isotope ratios and radiocarbon values. Linear fit and regression statistics for the relationship between co-registered $\delta^{13}$C and $^{14}$C shell samples (shown here as $\Delta R$ values).

Figure 7 | Relationship between winter NAO and shell $\Delta R$ values. $z$-scores of shell-based $\Delta R$ values (this study; orange) and Gulf Stream transport estimates (ref. 1) (blue) are compared with the raw data used in the wintertime NAO reconstruction (ref. 14) (red). Shell $\Delta R$ values and Gulf Stream transport data were fit with a smoothing spline function ($p$ parameter = 0.0003) to highlight the low frequency evolution and coherence of these series.
Methods
Shell collection. The shells used in this study were part of a collection of live, dead articulated, and dead single valves of *A. islandica* collected by trawling the seabed surface with a bespoke dredge on the North Icelandic shelf (Fig. 1) in June 2006 from the RV *Bjarni Sverrisson* (Cruise No. B05-2006). Shells were collected near the island of Grímsey (66° 31.59’ N, 18° 11.74’ W) at a water depth of 81–83 m (trawl B05AD03)39.

Radiocarbon analysis. To identify shells from long-lived animals that had been alive during the target period and that might therefore be used in an absolutely dated chronology, 24 of the largest and heaviest of the dead-collected shells were initially selected for AMS radiocarbon dating. The peristomial was removed by scraping the outer shell surface using a razor blade near the targeted region and an ~10–30 mg solid sample of shell carbonate was cut and removed from the outer shell surface for radiocarbon sampling. The shell samples were treated following a standard mollusc-rinsing procedure at Aarhus University AMS 14C Dating Centre (Denmark); to eliminate any possible surface contamination, the outer 25% of the shell was removed by etching in 1 M HCl. Any organic carbon incorporated in the shell carbonate was removed by treatment with a KMnO4 solution for 16–20 h at 80 °C. The CO2 was liberated with ~100% phosphoric acid in an evacuated vial at 25 °C. Part of the CO2 was used for 813C measurements; the remainder was converted to graphite for AMS 14C measurements on the Centre’s EN tandem accelerator by reduction with H2 with cobalt as a catalyst.

Shell chronology. Additional detailed methods regarding the construction of the master shell chronology are outlined in ref. 27. In brief, the shell valves were sectioned along the axis of maximum growth from the hinge tooth at the umbo to the outer shell margin. The exposed surface was ground and polished, then etched in one of two ways: either in a modified Mutvei solution30,35 or in 0.1 M HCl for 2 to 4 min (ref. 51). An acetate peel replica was taken of the etched surface from which discrete annual increments could be viewed under transmitted light and measured using dedicated software (see ref. 49 for additional details). Of the 24 dead-collected shells that were radiocarbon dated, 6 were dated before the target period and a further 4 could not be reliably measured because their increments could not be visualized with sufficient resolution. The other 14 were measured and cross-dated and, in all cases, their sclerochronologically determined calendar ages were found to be consistent with their calibrated radiocarbon ages. Growth in *A. islandica* is similar to growth in trees in that it is characterized by strong ontogenetic trends in increment width and variance35. These trends can be resolved with the same detrending techniques that are used in dendrochronology.

Calculated of ∆R. To determine the deviation in the local marine radiocarbon reservoir age (∆R) north of Iceland, the modelled ocean (via Marine09; see ref. 28) 14C value, for the sclerochronologically determined calendar year of the sample, was subtracted from the 14C shell value determined by AMS dating (see ref. 30 and Supplementary Data 1).

Updated ∆R values for shells 061294 and 061315. The individual specimen (shell 061294) reported here as having lived for 507 years has previously been reported with a lifetime of 405–410 years40. This adjustment was a consequence of a refinement in the method of increment counting22. Previously, when working with shells from UK waters with lifetimes of up to 260 years, measurements of the hinge-plate region were recommended31, because the increments there were less vulnerable to the disturbance caused by external shocks and were generally easier to visualize. *A. islandica* from the North Icelandic shelf, however, are more long-lived than those from UK waters23,27,21 and are also slightly smaller. In these shells, the small increment in the hinge plate can be so tightly packed that they can no longer be distinguished, and it is possible for groups of narrow increments to be counted as a single increment. Subsequent to the initial report of the longevity
