For economic and environmental reasons, dry forming is of increasing interest due to the shortening of process chains, cost savings and reduction of environmental pollution. The aim of these investigations is to examine to what extent chemical vapor deposited (CVD) diamond coatings are suitable for dry forming of aluminum and to identify the surface topology requirements for a low friction coefficient and low wear. Nine different surface topologies of CVD diamond coatings were tested in an oscillating ball-on-plate tribometer test against aluminum balls with a Hertzian contact stress of 759 MPa and 99,900 cycles. It could be concluded that the peak material volume (Vmp) of the diamond coating is the most important factor for achieving a low abrasion of aluminum as well as a low friction coefficient against aluminum. The Vmp should be smaller than 0.04 ml/m². Microcrystalline CVD diamond with a post-treated surface has great potential for dry forming of aluminum.

INTRODUCTION

Dry forming is of increasing interest for both economic and environmental reasons. Different approaches already lead to a possibility of dry forming. However, tool wear leads to a short tool life, so that dry forming is not yet competitive with oiled forming processes. Due to their high hardness, wear resistance and chemical inertness against aluminum, chemical vapor deposited (CVD) diamond coatings have excellent preconditions as tool coatings for dry forming. Tribological investigations show low coefficients of friction of CVD diamond coatings against different materials. Bhushan et al.¹ showed a decreasing coefficient of friction with decreasing roughness in the oscillating ball-on-plate test of aluminum balls against differently smoothly polished CVD diamond coatings. This thesis that both the wear rate and the coefficient of friction decrease with a decreasing surface roughness is supported by several publications. Erdemir et al.² concluded, on the basis of tribometer tests of differently rough polycrystalline diamond layers, that the higher the surface roughness, the higher the friction and the wear rate. The high coefficient of friction of rough polycrystalline CVD diamond coatings is attributed to abrasive ploughing and cutting effects of the sharp surface tips. A higher coefficient of friction in the running-in behavior with a subsequent reduction in the coefficient of friction is explained by the breaking-out and flattening of peaks. Erdemir³ concluded, based on further publications, that the general rule is that the smoother the diamond surface, the lower the coefficient of friction and the wear rate. Bögli et al.⁴ compared differently treated CVD diamond coatings (mechanically polished, laser polished, plasma polished) with nanocrystalline CVD diamond coatings in a tribometer test. Although the roughness of the surfaces was comparable, the mechanically polished diamond layers [arithmetical mean height (Ra) 35 nm] lead to by far the lowest coefficient of friction of 0.03 against monocrystalline ruby. The nanocrystalline CVD diamond coatings with a roughness of Ra 30 nm lead to the highest coefficient of friction of 0.57. This clearly shows that the roughness [Ra or the root mean square deviation (Rq)] is not a suitable parameter for establishing a clear correlation with the coefficient of friction and the wear rate.

The aim of this study was to find out whether a surface post-treatment of CVD diamond coatings is necessary for low wear and low friction in dry tribological contact with aluminum or whether a targeted adjustment of the process parameters and the associated crystal size and surface roughness is
sufficient. The following working hypothesis will be clarified: for mechanically polished and not post-processed polycrystalline diamond surfaces, a decrease in the wear rate of the aluminum counter body and the coefficient of friction can be predicted with the help of a topology size which takes into account the surface properties responsible for the mechanical clamping and the abrasive wear as a result of a decrease in the topology size.

METHODS

As substrate material, K10 hard metal discs of the type CTF12D with a diameter of 20.3 mm and a thickness of 3.0 mm ± 0.15 mm were used, consisting of 94% tungsten carbide and 6% cobalt. The discs where etched by Murakami reagent [K₂Fe(CN)₆:KOH:H₂O = 1:1:10] for 30 min and subsequently with Caro’s reagent (3 ml 96 wt.% H₂SO₄, 88 ml 40% w/v H₂O₂) for 60 s.⁵ The diamond nucleation was carried out with a dispersion of 200 ml isopropanol and 210 mg diamond powder with the average crystal size in the range of 0.25 μm to 0.50 μm, from the company Microdiamant AG. The substrates were put into the dispersion within an ultrasonic bath for 10 min and subsequently into isopropanol for 3 min. A laser-based plasma CVD process was used at atmospheric pressure without a vacuum chamber to deposit polycrystalline CVD diamond coatings, which is described in detail in Ref. 6. For the deposition of CVD diamond coatings with different surface topographies, methane and hydrogen with a total flow of 2 standard liters per minute (slm) was added to the argon plasma flame (26 slm). Nine different diamond coatings were deposited by varying the methane/hydrogen ratio, the deposition duration and temperature, which are listed in Table I. The different surfaces of the deposited coatings using the peak intensity of the G-band at 1332 cm⁻¹, were calculated, which is described in detail in Ref. 9. Micro-Raman spectroscopy (Renishaw system 1000) enabled the detection of diamond and graphite by using the excitation wavelength of 514 nm. The existence of diamond was proved by the measurement of the first order Raman line of the diamond according to the test certificate is shown in Table III. On one end of an aluminum rod, a hemisphere with a radius of 5 mm was turned on a lathe, which was used as the counter body. Before testing, the surfaces of the coated plates and round-ended aluminum pins were cleaned with ethanol in an ultrasonic bath for a duration of 5 min. After testing, the wear rates for the round-ended pins were calculated, which is described in detail in Ref. 9. Micro-Raman spectroscopy (Renishaw system 1000) enabled the detection of diamond and graphite by using the excitation wavelength of 514 nm. The existence of diamond was proved by the measurement of the first order Raman line of the diamond at 1332 cm⁻¹.¹⁰ The G-band at 1560 cm⁻¹ in the Raman spectra, was utilized to detect graphite in the deposited coatings. Equation 1 was used to calculate the diamond quality factors Q of the deposited coatings using the peak intensity of the diamond Raman line I_D and the intensity of the G-band peak I_G. The diamond quality factor allows for a semi-quantitative

RESULTS

The mean values of the friction coefficients over the first, middle and last half hour (9000 cycles) of the tribometer test are shown in Fig. 2. Of all coatings, the CVDD 10.25p coating shows the most constant behavior over the entire test period. The coefficients of friction of the CVD diamond coatings clearly show the influence of the coating surface in dry tribological contact with aluminum. At the beginning of the tribometer test, the coefficient of friction is between 0.13 and 0.58 depending on the coating surface. In the last half hour of the test, the coefficients of friction of the CVD diamond coatings are between 0.12 and 0.48.

The wear rates of the aluminum balls after the tribometer tests are shown in Fig. 3. It can be seen that the three diamond coatings with the largest crystal size, which were not post-treated, lead to the largest wear rates of the aluminum balls. The polished diamond coating CVDD 10.25p leads to the smallest wear rate of the aluminum ball of $4.5 \times 10^{-9} \text{mm}^3/\text{Nm}$.

The two coatings with the smallest mean crystal size CVDD 0.48 and CVDD 0.94 show coating delamination at the turning points of the oscillating ball-on-plate test. In Fig. 4 the delamination is shown for CVDD 0.94. This can only be detected at the turning points; in the remaining wear track neither layer detachments nor crack formations of the diamond coating are detected.

The calculated diamond quality factors before and after the tribometer test are shown in Fig. 5. The fact that in each case the diamond quality factor could be determined before and after the tribometer test shows that in no case was the diamond coating worn out in the center of the wear track. The tribometer test does not lead to a change of the diamond quality factor. Furthermore, it can be seen that the diamond quality factor increases with increasing mean crystal size. The coefficient of friction does not correlate with the diamond quality factor.

Figure 6 shows the coefficients of friction determined in the tribometer test as a function of various parameters for describing the surface roughness (core material volume (Vmc), reduced valley depth (Svk), peak extreme height (Sxp), and reduced peak height (Spk)). It is noticeable that in all four diagrams, two of the three mechanically polished samples differ from the other samples. These are the two samples which were mechanically polished by rubbing two diamond layers against each other (CVDD 8.89r and CVDD 1.91r). The third mechanically polished coating is the mirror polished coating CVDD 10.25p, which results in the lowest friction coefficient against the aluminum counter body.

The mean coefficient of friction as a function of the arithmetical mean height $S_a$ as well as of the peak material volume $V_{mp}$ is shown in Fig. 7. A comparable relationship can be recognized. However, it is noticeable that two mechanically polished coatings are not in line with the relationship in the diagram of the arithmetical mean height. The friction coefficient decreases with a decreasing $V_{mp}$ and saturates over a $V_{mp}$ value of 0.1 ml/m$^2$.

The same behavior, that two mechanically polished diamond coatings do not show the relationship of the unpolished coatings, can be seen regarding the wear rate of the aluminum ball as a function of the $S_a$ in Fig. 8a. In contrast, the wear rate of the aluminum ball as a function of the $V_{mp}$ values (see Fig. 8b) shows a clear correlation for both unpolished and mechanically polished diamond coatings. A decreasing $V_{mp}$ value leads to a decreasing wear rate down to 0.04 ml/m$^2$. 

Fig. 2. The friction coefficient values for 9000 cycles are averaged and plotted for the first 9000 cycles, 9000 cycles in the middle of the test, and the last 9000 cycles of tribological examination

DISCUSSION

As described in the introduction, some publications suggest that the lower the surface roughness of the CVD diamond layer, the lower the coefficient of friction and wear rate. Other publications doubt the direct relationship because the relationship is not present, especially in the comparison between polished and untreated CVD diamond coatings. Hayward et al. questions the
measurement method of line roughness. Different measuring tips are used in different publications, which leads to different results for the same surfaces. In this work, instead of line roughness, surface roughness was measured with a laser scanning confocal microscope. This enables the evaluation of a large number of other surface roughness parameters.

The surface of the untreated CVD diamond layers differs mainly in the different crystal sizes. This leads to a scaling of most surface roughness parameters. The mechanically polished CVDD 10.25p coating achieves low values for all parameters due to the mirror-polished surface, so that in the diagrams it fits into the course of a decreasing coefficient of friction due to decreasing surface roughness parameters. The rubbed CVD diamond coatings lead to inhomogeneous roughness parameters. The deep valleys of the microcrystalline CVD diamond layer are still present, but the protruding peaks have been greatly reduced, resulting in plateaus. The difference becomes particularly clear in Fig. 7 when comparing the CVDD 9.70 and the CVDD 8.89r coatings. Rubbing two CVD diamond coatings with a mean diamond crystal size of 8.89 µm against each other reduces the mean arithmetic height, Sa, from 2.09 µm to 1.47 µm (by 30%), which is still the second highest value compared to the other coatings (Fig. 7a the two values with the highest Sa). The peak material volume, however, was reduced from 0.161 ml/m² to 0.041 ml/m² (by 75%) and thus from the second highest to the second lowest value (see Fig. 7b). In the diagram of the coefficient of friction as a function of the Vmp, the correlation can be seen that an increase in the Vmp leads to a near-to-linear increase in the coefficient of friction. From a Vmp value of about 0.1 ml/m², the coefficient of friction becomes saturated at about 0.5. Furthermore, the diagram shows that it is not to be expected that the coefficient of friction between the aluminum alloy EN AW 5083 and diamond will fall below 0.1.
From the diagram in Fig. 8 it can be concluded that the volume of the top 10% of the surface to which the peak material volume (Vmp) refers is the relevant factor for the abrasion of aluminum. The hypothesis, “For mechanically polished and non-polished polycrystalline diamond surfaces, a decrease in the wear rate of the aluminum counter body and the coefficient of friction due to a decrease in the topology size can be predicted with the help of a topology size which takes into account the surface properties responsible for the mechanical interlocking and the abrasive wear,” could be confirmed. The topology size searched for, which for non-polished and mechanically polished CVD diamond coatings is equally capable of estimating the coefficient of friction as well as the wear rate of the aluminum counter body in the dry oscillating ball-on-plate tribometer test, is the peak material volume.

For diamond coatings in dry contact with the aluminum alloy EN AW-5083, it can be concluded from the investigations that in order to minimize the wear rate of the aluminum counter body, a peak material volume of less than 0.04 ml/m² should be aimed for. The two untreated CVD diamond coatings with the lowest Vmp values (CVDD 0.48 and CVDD 0.94) exhibit layer delamination at the turning points. This means that they do not withstand repeated static friction with the chosen coating properties. For this reason, without further coating process development, the deposition of microcrystalline CVD diamond layers with subsequent post-treatment of the surface is recommended in order to achieve a peak material volume of less than 0.04 ml/m² for dry piece goods processes of aluminum workpieces.

CONCLUSION

The peak material volume (Vmp) is equally capable of estimating, for non-polished and mechanically polished CVD diamond coatings, the coefficient of friction as well as the wear rate of the aluminum counter body in the dry oscillating ball-on-plate tribometer test. For dry piece goods processes of aluminum workpieces, the deposition of microcrystalline CVD diamond layers with subsequent post-treatment of the surface is recommended in order to achieve a peak material volume of less than 0.04 ml/m² in order to minimize the wear rate of the aluminum counter body. The lower the Vmp value, the lower the coefficient of friction, so that a minimum Vmp value must be achieved in the case of a desired minimum coefficient of friction.
