Revisiting Metric Learning for Few-Shot Image Classification

Xiaomeng Li, Lequan Yu, Chi-Wing Fu, Meng Fang, and Pheng-Ann Heng

Abstract—The goal of few-shot learning is to recognize new visual concepts with just a few labeled samples in each class. Recent effective metric-based few-shot approaches employ neural networks to learn a feature similarity comparison between query and support examples. However, the importance of feature embedding, i.e., exploring the relationship among training samples, is neglected. In this work, we present a simple yet powerful baseline for few-shot classification by emphasizing the importance of feature embedding. Specifically, we revisit the classical triplet network from deep metric learning, and extend it into a deep K-tuplet network for few-shot learning, utilizing the relationship among the input samples to learn a general representation learning via episode-training. Once trained, our network is able to extract discriminative features for unseen novel categories and can be seamlessly incorporated with a non-linear distance metric function to facilitate the few-shot classification. Our result on the miniImageNet benchmark outperforms other metric-based few-shot classification methods. More importantly, when evaluated on completely different datasets (Caltech-101, CUB-200, Stanford Dogs and Cars) using the model trained with miniImageNet, our method significantly outperforms prior methods, demonstrating its superior capability to generalize to unseen classes.

Index Terms—Few-shot learning, metric learning, feature representation, deep learning.

I. INTRODUCTION

LEARNING from a few data is a hallmark of human intelligence, however, it remains a challenge for modern deep learning systems. Recently, there has been a growing interest in few-shot learning [1,26], which aims to recognize new visual concepts with just a small amount of labeled data for training. In other words, the goal of few-shot learning is to classify unseen data instances (query examples) into a set of new categories, given just a small number of labeled instances in each class (support examples). In this work, we focus on the case of few-shot classification, where only a few labeled examples per class are given.

Obviously, naively fine-tuning a model on the novel labeled data would easily overfit the few given data. Hence, data augmentation and regularization [27,28] are often employed to somehow relieve the overfitting. Later, the meta-learning paradigm [3,4,29,30] shed light to the few-shot learning problem; several metric learning-based methods [2,31,33] were developed. For instance, the matching network [32] uses an end-to-end trainable k-nearest neighbors algorithm on the learned embedding of the few labeled examples (support set) to predict the classes of the unlabeled samples (query set), while the prototypical network [2] further builds a pre-class prototype representation. More recently, Sung et al. presented the relation network [33], which learns a nonlinear distance metric via a shallow neural network instead of using a fixed linear distance metric, e.g., Cosine [2] and Euclidean [2]. These methods utilize deep networks to extract expressive deep features, they do not take full advantages of the relationship between query and support examples. However, the importance of feature embedding should map the similar samples close to one another and dissimilar ones far apart. This is well aligned with the philosophy of triplet-like learning. However, the general triplet network only interacts with a single negative sample per update, while few-shot classification requires a comparison with multiple query samples, typically of different classes. Hence, we formulate an improved triplet-like metric learning, namely the deep K-tuplet Network, to improve few-shot classification. Particularly, the deep K-tuplet Network generalizes the triplet network to allow joint comparison with K negative samples in each mini-batch. It makes the feature embedding learning process more faithful to the few-shot classification problem with improved feature generalization. Moreover, we present the semi-hard mining sampling technique, an effective sampling strategy to sample informative hard triplets. Hence, we can speed up the convergence and stabilize the training procedure.

Our technique is simple yet powerful, and can be seamlessly incorporated with the learnable non-linear distance metric [33] for few-shot classification. To demonstrate the generalization capability of our presented few-shot classification framework, we train our model on the miniImageNet dataset [32], and conduct few-shot classification, not only on the miniImageNet testing data, but also on other novel classes in other datasets.
(e.g., Caltech-101, CUB-200, Stanford Dogs and Cars). Experimental results demonstrate that our method effectively generalizes for unseen novel class samples, even across different datasets.

The main contributions of this work are threefold:

1) We present a simple and powerful baseline method to investigate the importance of feature embedding for few-shot classification, where the effectiveness of feature embedding is neglected by previous works.

2) We present the deep K-tuplet Network to effectively learn the discriminative feature embedding on unseen class samples for few-shot learning. Our method outperforms other metric-based methods and achieves competitive performance over other meta-based methods on the miniImageNet.

3) More importantly, prior works evaluated the few-shot learning within one dataset, i.e., the novel classes and base classes are sampled from the same dataset. This experiment setting may not be representative in the real world setting. We establish a new experimental setting for evaluating the cross-domain generalization ability for few-shot classification algorithms. Our result generalized on CUB-200, Stanford Dogs, Stanford Cars and Caltech-101 excels other methods, showing the excellent cross-domain generalization capacity of our method.

II. RELATED WORK

Few-shot learning is an important area of research. Early works on the few-shot learning focused on generative models and inference strategies. In [34], the authors assumed that one can utilize knowledge coming from previously-learned classes to make predictions on new classes only with one or few labels. However, these methods do not involve deep learning. Recently, with the success of deep learning, significant progress has been achieved in the few-shot learning area.

A. Meta-learners for Few-Shot Learning

One category of the few-shot learning is meta-learner based methods. The meta-learning algorithm (MAML) used a model agnostic meta-learner to train a good basic model on a variety of training tasks, such that given a new task with only a few training samples, a small amount of gradient steps is sufficient to produce a good generalization model. Ravi & Larochelle further proposed an LSTM-based meta-learning model to learn the optimization algorithm of training a network, where the LSTM updates the weights of a classifier for a given episode. Both methods, however, need to fine-tune the basic model on the target problem. Munkhdalai & Yu introduced a novel meta-learning architecture that learns meta-level knowledge across tasks and produces a new model via fast parameterization for rapid generalization. Santoro et al. introduced a memory-augmented neural network to quickly encode and retrieve new data and make accurate predictions with only a few samples. Lately, some other works focused on meta-learners for few-shot classification. However, all these methods needs to fine-tune or update the parameters for new unseen tasks, while our method performs the target tasks based entirely on feed forward without requiring further parameter updates.

B. Deep Metric Learning

Our work is related to deep metric learning, which involves a large volume of metric learning methods. Below, we briefly review the more relevant ones. The goal of metric learning is to minimize the intra-class variations and maximize the inter-class variations. Early works use the siamese architecture to capture the similarity between images. The recent works adopted the deep networks as the feature embedding function, and used triplet losses instead of pairwise constraints to learn the metric. These metric learning strategies have been widely used in image retrieval, face recognition, and person re-identification. More recently, Wu et al. presented a feature embedding method based on neighborhood component analysis. These works show that combining deep models with proper objectives is effective in learning the similarities. Unlike these methods, we consider using triplet-like networks to improve the feature discrimination on the unseen class images for few-shot learning problem.

C. Metric Learning for Few-shot Learning

The second branch are metric based approaches. Metric learning based methods learn a set of project functions (embedding functions) and metrics to measure the similarity between the query and samples images and classify them in a feed-forward manner. The key difference among metric-learning-based methods lies on how they learn the metric. Koch et al. presented the siamese neural networks to compute the pair-wise distance between samples, and used the learned distance to solve the one-shot learning problem via a K-nearest neighbors classification. Vinyals et al. designed an end-to-end trainable k-nearest neighbors using the cosine distance on the learned embedding feature, namely matching network. Lately, Snell et al. extended the matching network by using the Euclidean distance instead of the cosine distance and building a prototype representation of each class for the few-shot learning scenario, namely prototypical network. Mehrotra & Dukkipati trained a deep residual network together with a generative model to approximate the expressive pair-wise similarity between samples.

Recently, Ren et al. extended the prototypical network to do semi-supervised few-shot classification, while Garcia et al. defined a graph neural network to conduct semi-supervised and active learning. Sung et al. argued that the embedding space should be classified by a nonlinear classifier and designed the relation module to learn the distance between the embedded features of support images and query images. The relation network extends the matching network and prototypical network by including a learnable nonlinear comparator. Notably, the prototypical networks, siamese networks, and relation net all adopt the episode-based training strategy, where each episode is designed to mimic few-shot learning. More recently, Li et al. proposed
category traversal module (CTM) to look at all categories in the support set to find task-relevant features. Li et al. [6] present the deep nearest neighbor neural network to improve the final classification in the few-shot learning. Although the excellent performance achieved in the few-shot classification, the importance of feature embedding have not paid sufficient attention.

III. Method

A. Overview

Few-shot classification involves three datasets: a training set $D_{train}$, a support set $D_{supp}$, and a query set $D_{query}$. In short, we want to train a model to learn transferable knowledge from $D_{train}$, and apply the knowledge in the testing phase to classify the samples in $D_{query}$ given $D_{supp}$.

- $D_{train} = \{(x_i, y_i)\}_{i=1}^N$ is used for training the model, where $x_i$ is a training image, $y_i \in \mathcal{C}_{train}$ is the label of $x_i$, and $N$ is the number of training examples.
- $D_{supp} = \{(x_j, y_j)\}_{j=1}^M$ is the set of $M$ labeled examples given in the testing phase, where $y_j \in \mathcal{C}_{supp}$ is the label of $x_j$ but $\mathcal{C}_{train} \cap \mathcal{C}_{supp} = \emptyset$.
- Given $D_{query} = \{x_i\}_{i=1}^N$, the goal of few-shot classification is to classify the samples in $D_{query}$.

Note that the support set $D_{supp}$ and the query set $D_{query}$ share the same label space. If the support set has $K$ labeled examples for each of the $C$ classes in $\mathcal{C}_{supp}$, i.e., $M = C \times K$, then the few-shot problem is called $C$-way $K$-shot.

Figure 1 overviews our few-shot learning framework. First, we meta-learn a transferable feature embedding through the deep K-tuplet network with the designed $K$-tuplet loss from the training dataset. The well-learned embedding features of the query image and samples in the support set are then fed into the non-linear distance metric to learn the similarity scores. Further, we conduct few-shot classification based on these scores.

B. Meta-learn Feature Embedding

Such nonlinear mapping should be generalizable to work with samples of novel classes, meaning that the mapping should preserve the class relationship on the unseen class samples in $D_{supp}$ and $D_{query}$. We adopt a triplet-like network to learn the feature embedding on $D_{train}$.

Specifically, for an input image $x_i$, function $f(\cdot; \theta) : \mathcal{X} \rightarrow \mathbb{R}^d$ maps $x_i$ to an embedding vector $f(x_i)$, where $\theta$ denotes the parameters of the embedding function; $d$ is the dimension of the embedded features, and $f(x_i)$ is usually normalized to unit length for training stability and comparison simplicity. To learn parameter $\theta$, the traditional triplet loss is widely used, where the objective is based on a relative similarity or distance comparison metric on the sampled pairs. In short, the training samples are randomly selected to form a triplet $(x_a, x_p, x_n)$ with an anchor sample $x_a$, a positive sample $x_p$, and a negative sample $x_n$. The label of the selected samples in a triplet should satisfy $y_a = y_p \neq y_n$. The aim of the loss is to pull $f(x_a)$ and $f(x_p)$ close to each other, while pushing $f(x_a)$ and $f(x_n)$ far apart.

However, the above traditional triplet loss interacts with only one negative sample (and equivalently one negative class) for each update in the network, while we actually need to compare the query image with multiple different classes in few-shot classification. Hence, the triplet loss may not be effective for the feature embedding learning, particularly when we have several classes to handle in the few-shot classification setting. Inspired by [50], we generalize the traditional triplet loss to a tuplet loss with $K$-negatives, namely $K$-tuplet loss, to allow simultaneous comparison jointly with $K$ negative samples, instead of just one negative sample, in one mini-batch. This extension makes the feature comparison more effective and faithful to the few-shot procedure, since each update, the network can compare a sample with multiple negative classes altogether.

In particular, we randomly choose the $K$ negative samples
\(x_0, \ldots, x_n, i = \{1, 2, \ldots, K\}\) to form into a triplet. Accordingly, the optimization objective is formulated as:

\[
L(x_0, x_p, x_n, i) = \frac{1}{K} \sum_{i=1}^{K} \left[ \|f_0 - f_p\|^2 - \|f_0 - f_n\|^2 + \alpha \right] + \beta \max(0, -\alpha),
\]

where \(\cdot\) is the hinge loss function and \(\alpha\) is the hyperparameter margin, and we write \(f(x)\) as \(f\) to omit \(x\) for simplicity. For the anchor sample \(x_0\), the optimization shall maximize the distance to the negative samples \(x_n, i\) to be larger than the distance to the positive sample \(x_p\) in the feature space. To form one mini-batch to train the network, we randomly select \(B\) anchor samples from the training set, where \(B\) is batch size. For each anchor sample \(x_0\), we then randomly select another positive sample \(x_p\) of the same class as \(x_0\) and further randomly select \(K\) other negative samples whose classes are different from \(x_0\). Among the \(K\) negative samples, their class labels may be different. Compared with the traditional triplet loss, each forward update in our \(K\)-tuplet loss considers more inter-class variations, thus making the learned feature embedding more discriminative for samples from different classes.

C. Efficient Training with Semi-hard Mining

When training with the \(K\)-tuplet loss, the individual update of one mini-batch may be unstable. This is because when the model starts to converge, the well-learned samples obey the margin and cannot contribute to the gradients in the learning process. This phenomenon degrades the model capacity and slows down the convergence of the training. We, thereby, design a semi-hard mining strategy to sample more informative hard triplets in each mini-batch when the model starts to converge. Specifically, we first randomly sample \(B\) triplets according to the strategy in Section III-B. Then, we intentionally check if the sampled triplets obey the margin or not. We remove those well-learned triplets that have already satisfied the margin, and sample remainder triplets from the training sets to form a mini-batch. The final objective is then calculated on the new mini-batch. From our experiments, we can see that this semi-hard mining strategy helps improve the training efficiency and contributes to the learning of feature embedding.

D. Non-linear Distance Metric Learning

Furthermore, we adopt the non-linear distance metric module \([33]\) to learn to compare the embedded features in few-shot classification. Given image \(x_s\) from the support set and image \(x_q\) from the query set, their similarity score is learned by concatenating \(f_\theta(x_q)\) and \(f_\theta(x_a)\) and then feeding the combined feature into a non-linear distance metric. The non-linear distance metric has two convolutional blocks and two fully-connected layers. Each convolutional block consists of a \(3 \times 3\) convolution with 64 channels followed by a batch normalization, an ReLU activation function, and a \(2 \times 2\) max-pooling. The fully-connected layers have 8 and 1 outputs, followed by a sigmoid function to get the final similarity scores between the query image \(x_q\) and samples in the support set.

In the end, our non-linear distance metric learns to produce the similarity score by calculating the mean square error loss, following the same spirit as \([33]\).

Figure 2 shows the detailed network architecture of our non-linear metric learning module. The input is the concatenation of features from the images of the support set and the query set. The output is the similarity scores of the query images with images in the support set. The few-shot classification prediction is the label of the image that has the maximum similarity score in the support set.

E. Technique Details

We employed the ResNet34 architecture \([57]\) for learning the feature embedding. When meta-learning the transferable feature embedding, we used Adam optimizer \([58]\) with a learning rate of 0.001 and a decay for every 40 epochs. We totally trained 100 epochs and adopted the semi-hard mining strategy when the loss starts to converge (at around 80 epochs). To learn the non-linear distance metric, we followed the episode-based strategy and also employed the Adam optimizer with a learning rate of 0.001. Different from the general episode sampling procedure, we sampled multiple episodes to form each mini-batch to train the non-linear distance metric. This strategy increases the data diversity, i.e., the number of different class samples) and makes the training more stable.

We evaluate the accuracy of few-shot classification by averaging the randomly-generated episodes from the training set, following \([2]\). For 5-way 1-shot test, each query image is compared with five samples in the support set. The prediction is the label of the sample that has the maximum similarity score within the support set. For 5-way 5-shot test, we sum the features of all the samples in each class in the support set as the feature map of the class and then follow the same procedure with 5-way 1-shot setting to get the query image label.

IV. EXPERIMENTS

We first evaluate our few-shot classification method on the public miniImageNet dataset. We then show the generalization of our approach by directly evaluating on completely different datasets using the model trained with miniImageNet. Lastly, we extensively analyze the different components of our method.
### Table I

**AVERAGE FEW-SHOT CLASSIFICATION ACCURACIES (%) ON THE MINIIMAGENET.** Note that '-' denotes not reported. All accuracy results are averaged over 600 test episodes and are reported with 95% confidence intervals. We bold up top two results.

| Model                   | Year     | 5-way Acc. |      |       |      |      |

### A. Few-shot Classification on the MiniImageNet

The MiniImageNet dataset is derived from the ILSVRC-12 dataset [63], consisting of 60,000 color images with 100 classes and 600 samples per class. In order to directly compare with state-of-the-art algorithms, we follow the splits introduced by Ravi and Larochelle [4], with 64, 16 and 20 classes for training, validation and testing, respectively. The validation dataset is used for monitoring generalization performance of the network only and not used for training the network.

We compare our approaches with several state-of-the-art methods reported on the MinImageNet [9, 32, 33], as shown in Table I. Most of the existing methods employed the shallow neural network, i.e., four convolutional layers, to extract the feature. Since our method is based on the well-learned feature embedding, the shallow embedding network did not make adequate usage of our method’s expressive capacity. Thus, we follow the recent works [11, 37, 61] to use a deeper embedding network, i.e., ResNet, to prevent the underfitting.

Compared with metric-based methods, we can see that our method achieves the highest accuracy on 5-way 1-shot setting and very competitive accuracy on 5-way 5-shot setting, as shown in Table I. We report the few-shot classification accuracy of our method using the K-NN classifier with the Euclidean distance on the embedded feature; see Ours+Euclid in Table I. In this setting, we remove the non-linear metric and use K nearest neighbors (K=1) on the embedded features of query images and support images for classification. It is observed that the Euclid version of our method still achieves the competitive results, showing the generalization and discrimination of the learned feature embedding on unseen novel categories. In Figure 5, we show the 10 nearest neighbor images of the query image on the MiniImageNet testing dataset.
with the Euclid distance of our learned embedding features. We can see our feature embedding preserves apparent visual similarity better and facilitates the accurate recognition.

### B. Generalizing to Other Datasets

A new dataset may present data distribution shift, and the classification accuracy of widely used models drops significantly [64]. In current setting of few-shot classification, most methods conduct training and testing phases within the same dataset, i.e., miniImageNet. Although the training classes and testing classes do not share the same label space, they still come from the same data distribution. While, in the real world, the unknown novel classes may come from an agnostic data distribution. Therefore, to validate the generalization capability of our approach, we conduct the few-shot classification on novel classes from the following four datasets using the model trained on the miniImageNet training dataset.

- **Caltech-101.** The Caltech-101 dataset [34, 65] contains objects belonging to 101 categories. Each category contains about 40 to 800 images. Most categories have about 50 images.
- **Caltech-UCSD Birds-200-2011 (CUB-200).** Caltech-UCSD Birds 200 (CUB-200) [66] contains photos of 200 bird species (mostly North American). In this fine-grained dataset, subtle differences between very similar classes can hardly be recognized even by humans.
- **Stanford Dogs.** The Stanford Dogs dataset [67] contains images of 120 breeds of dogs from around the world. This dataset has been built using images and annotation from ImageNet for the task of fine-grained image categorization.
- **Stanford Cars.** The Stanford Cars [68] contains 16,185 images of 196 classes of cars.

Following the same data selection principal as miniImageNet [32], we randomly select 20 classes in each dataset as the test dataset. Note that the test datasets do not share the same label space with the training images. Please see the section I in the supplementary files for detailed selected class in each dataset. Without any fine-tuning, we directly use the model trained on the miniImageNet training dataset to perform few-shot classification on the new datasets. Table II shows the classification performance of Relation Net, Proto Net, Cosface embedding [62], and our method on the four datasets. The results are achieved by the model with the same network backbone. It is observed that our model performs consistently better than Relation Net, Proto Net and Cosface embedding on all four datasets. To compare the results on the different datasets, the accuracy on Caltech-101 are much higher than the results of other three datasets, even than the miniImageNet testing dataset. This is because the Caltech-101 contains a single object with pure background and it is much easier to be recognized, while the CUB-200, Stanford Dogs and Stanford Cars have relative complex background. We visualize the results of 5-way 5-shot setting achieved by Relation Net and our model in Figure 4. We can see that our method is very discriminative to similar objects. These comparisons clearly demonstrate that our approach is able to learn more generalized transferable features for few-shot classification among different datasets. Please see more visualized results in the section III in the supplementary files.

### C. Analysis of Our Method

To better understand our method, we conduct the following experiments on the miniImageNet dataset.

1) **Results with Different Network Backbones:** We compare the few-shot classification performance of our approach under different network backbones, i.e., AlexNet [69], VGG [70], and ResNet [57]. We conduct experiments on the miniImageNet with the same experiment setting for network architectures. Note that the performance is evaluated by one
nearest neighborhood (1-NN) with Euclidean distance to better show the influence of different network backbones. From the results in Table IV, it is observed that the classification accuracy of AlexNet and VGG11 are similar, while the few-shot classification accuracy is largely improved (about 10% improvement in both 5-way 1-shot and 5-way 5-shot settings) with a more deeper ResNet. The reason may be that we can extract more representative features with the deeper ResNet and thus improve the accuracy on few-shot testing. ResNet18 and ResNet34 achieve similar results on 5-way 5-shot evaluation, but ResNet34 achieves a bit higher performance on 5-way 1-shot setting. However, the classification accuracy would be decreased as the model complexity continues to grow (e.g., from ResNet34 to ResNet50). This finding indicates that too many parameters may lead to overfitting on the training tasks and thus decrease the classification results on novel categories. Therefore, an effective network backbone can indeed contribute to the transferable feature extraction and improve the accuracy on few-shot classification. Overall, in our experiment, we choose the ResNet34 as the network backbone.

2) The Tuplet-loss with Different Negative Pairs: We compare the performance of our method with different \( K \) in the tuplet loss, where \( K \) is the number of negative samples from different classes in each tuplet. We also report the classification accuracy using the one nearest neighborhood (1-NN) classifier with Euclidean distance. As shown in Table IV, the accuracy is a little low if we set \( K \) as 1 in the tuplet loss (equivalent to traditional triplet loss). The classification accuracy is improved with a larger \( K \), since the anchor sample interacts with more samples in one mini-batch and makes the gradient more stable. In another aspect, the classification accuracy would
Figure 5. T-SNE visualization of features in Proto Net, Relation Net and our method on the same set of samples in the test dataset (example 1).

Figure 6. T-SNE visualization of features in Proto Net, Relation Net and our method on the same set of samples in the test dataset (example 2).

Table IV

| Number of $K$ | 5-way Acc. | 1-shot | 5-shot |
|---------------|------------|--------|--------|
| $K=1$         | 40.15 ± 0.75 | 54.62 ± 0.68 |
| $K=4$         | 51.22 ± 0.81 | 65.66 ± 0.68 |
| $K=5$         | **54.46 ± 0.89** | **68.15 ± 0.65** |
| $K=8$         | 53.17 ± 0.81 | 66.77 ± 0.68 |
| $K=16$        | 46.03 ± 0.79 | 60.02 ± 0.67 |

be saturated with a bigger $K$, and we can achieve the best performance when setting $K$ to 5.

3) Effects of Semi-hard Mining: Table V shows the effects on our feature embedding when trained with and without semi-hard mining. We report the few-shot classification accuracy on the miniImageNet testing data with the two resulting learned feature embedding. It is observed that with semi-hard mining, the few-shot classification accuracy on both 1-shot and 5-shot scenarios can be further improved by relative 1.6% and 1.0% respectively, thus demonstrating its effectiveness to improve feature embedding learning.

4) The Analysis of Different Margin: We also investigate the effect of different margin $\alpha$ in the tuplet loss and the results of our whole framework with different settings are shown in Table VI. The experimental results show that with margin 0.5, the feature embedding in this task is the best. A smaller margin...
5) The Results with More Training Classes: We would like to explore whether the few-shot classification accuracy will increase if more training classes are available. Thus, we conduct experiments with additional class images from the ImageNet dataset. Note that the additional dataset does not share the same labels with the testing images. Table VII presents the accuracy on the miniImageNet testing dataset of our method trained with different number of training classes. We can see that our method can be further improved with extra training classes data available. This is conform with our expectation that we can learn more transferable generalized feature embedding from more training samples. Based on the generalized feature, we can further improve the few-shot classification accuracy on the novel categories.

VI. CONCLUSION

In this work, we revisit the metric learning and propose a simple and effective K-tuplet network for few-shot learning. We present an efficient K-tuplet network to utilize the relationship of training samples to learn the transferable feature embedding that performs well not only on the training samples but also on the novel class samples. Built on top of this generalized feature embedding, we can largely improve the few-shot classification accuracy. Our method is simple yet effective, and outperforms other metric-based few-shot classification algorithms on the public benchmark dataset. More importantly, our method can generalize very well to the novel categories even on other four datasets.
