(September 10, 1999)

We study a confined mixture of bosons and fermions in the regime of quantal degeneracy, with particular attention to the effects of the interactions on the kinetic energy of the fermionic component. We are able to explore a wide region of system parameters by identifying two scaling variables which completely determine its state at low temperature. These are the ratio of the boson-fermion and boson-boson interaction strengths and the ratio of the radii of the two clouds. We find that the effect of the interactions can be sizeable for reasonable choices of the parameters and that its experimental study can be used to infer the sign of the boson-fermion scattering length. The interplay between interactions and thermal effects in the fermionic kinetic energy is also discussed.

I. INTRODUCTION

The achievement of Bose-Einstein condensation in trapped gases \cite{1,2} has opened new opportunities for investigating the low temperature behaviour of dilute quantum systems. Recent experimental studies have been also addressed to the search of degeneracy effects in Fermi gases \cite{4,5} and in mixtures of bosons and fermions \cite{6}. First experimental evidences of these effects have been recently reported in \cite{7}. Due to the Pauli exclusion principle the effects of the interactions in a Fermi gas are much weaker than for a Bose condensate \cite{8,9,10,11,12,13}. Therefore, the kinetic energy dominates the behaviour of the Fermi gas and is a clear indicator of its quantum degeneracy.

Interest in boson-fermion mixtures is stimulated by the fact that, whereas in a one-component spin-polarized Fermi gas the absence of interactions leads to long thermalization times which hamper the process of evaporative cooling, the collisions between the two species in a mixture can ensure fast thermalization (the so-called sympathetic cooling \cite{14,15,16}). The kinetic energy of the Fermi component in such a mixture could be measured by time-of-flight techniques in an ideal experiment in which the confining potential is suddenly switched off after a fast expulsion (i.e. on a time scale shorter than the boson-fermion collision time) of the bosons from the trap. In this way one can avoid the effects of the interactions during the expansion of the gas. Alternatively, the kinetic energy could be obtained from inelastic photon scattering at high momentum transfer as recently shown in the case of a trapped Bose gas \cite{17}.

In this paper we analyze the behaviour of the kinetic energy of the fermionic component in a boson-fermion mixture. We find that the kinetic energy can be significantly affected by the interactions of the Fermi gas with the Bose-Einstein condensed cloud for reasonable choices of the system parameters. An important consequence of this purely quantum effect is that one can measure the sign and the strength of the boson-fermion scattering length by using the Bose component as a tunable device to change the effective potential felt by the fermions \cite{18}. We assume a positive boson-boson scattering length, with a view to applications to mixtures of Rb-K and Na-K.

II. INTERACTING FERMI-BOSE MIXTURES

For the description of the mixture at finite temperature we adopt the semiclassical three-fluid model already developed in ref. \cite{19}. We consider a system of $N_f$ fermions of mass $m_f$ and $N_b$ bosons of mass $m_b$ confined by external potentials $V_{ext}^f(r) = \frac{1}{2} m_f \omega_f^2 r^2$ with frequencies $\omega_f$ and $\omega_b$. The external potentials are assumed to be spherically symmetric, the asymmetric case requiring simply a change of variables in the framework of the semiclassical approximation that we adopt. We include the interaction between bosons through the scattering length $a_{bb}$ and the interaction between bosons and fermions through the scattering length $a_{bf}$. By assuming that a single spin state is trapped for each component of the mixture, we can safely neglect the fermion-fermion interaction which is inhibited by the Pauli exclusion principle. Extensions to multi-spin configurations can be naturally made within the present formalism. In the following we will neglect the possibility of a superfluid phase for the fermionic component (for
potential felt by the fermions takes the simplified form:

\[ n_f(r) = \int \frac{d^3p}{(2\pi\hbar)^3} \left( \exp[\beta\left(\frac{p^2}{2m_f} + V_{eff}^f(r) - \mu_f\right)] - 1 \right) \]

and

\[ n_{nc}(r) = \int \frac{d^3p}{(2\pi\hbar)^3} \left( \exp[\beta\left(\frac{p^2}{2m_b} + V_{eff}^b(r) - \mu_b\right)] - 1 \right) \]

Here, the effective potentials acting on the thermal boson cloud and on the fermions are given by

\[ V_{eff}^b(r) = V_{ext}^b(r) + 2g_{bb}n_c(r) + 2g_{bb}n_{nc}(r) + g_{bf}n_f(r) \]

and

\[ V_{eff}^f(r) = V_{ext}^f(r) + g_{bf}n_c(r) + g_{bf}n_{nc}(r) \]

The chemical potentials \( \mu_b \) and \( \mu_f \) are determined by the normalization conditions

\[ N_b = \int (n_c(r) + n_{nc}(r)) d^3r \]

and \( N_f = \int n_f(r) d^3r \), which ensure the self-consistent closure of the model.

Equations (1) and (3) have been derived from a grand-canonical Hamiltonian in which the interactions are included in a mean-field Hartree-Fock approximation, by employing the semiclassical approximation for the bosonic thermal cloud and for the fermions and by taking the strong coupling limit \( N_b a_{bb}/a_{ho} \gg 1 \) for the wave-function of the condensate, with \( a_{ho} = (\hbar/m_b\omega_b)^{1/2} \) the bosonic harmonic oscillator length. Upon averaging the Hamiltonian on the equilibrium state of the system at finite temperature we obtain the energy as the sum of various contributions: the kinetic and the external confinement energy for each of the species, as well as the boson-boson and boson-fermion interaction terms. One has

\[ E = E_{kin}^f + E_{kin}^b + E_{int}^f + E_{int}^b + E_{ext}^b + E_{ext}^f + E_{int}^b \]

\[ = \frac{3}{2} \frac{m_f}{2\pi\hbar^2} \left( \frac{m_f}{2\pi\hbar^2} \right)^{3/2} \beta^{-5/2} \int f_5/2(z_f) d^3r + \frac{3}{2} \frac{m_b}{2\pi\hbar^2} \left( \frac{m_b}{2\pi\hbar^2} \right)^{3/2} \beta^{-5/2} \int g_5/2(z_b) d^3r + \]

\[ \int V_{eff}^b(r) (n_c(r) + n_{nc}(r)) d^3r + \int V_{eff}^f(r) n_f(r) d^3r + \]

\[ \frac{g_{bb}}{2} \int (n_e^2(r) + 2n_{nc}^2(r) + 4n_c(r)n_{nc}(r)) d^3r + g_{bf} \int (n_c(r) + n_{nc}(r)) n_f(r) d^3r \]

where

\[ f_p(z) = \Gamma(p)^{-1} \int z^{p-1} dy/(z^{-1} e^y + 1), \]

\[ g_p(z) = \Gamma(p)^{-1} \int z^{p-1} dy/(z^{-1} e^y - 1) \]

are the usual Fermi and Bose functions and \( z_{f,b} = \exp(\beta(\mu_{f,b} - V_{eff}^{f,b}(r))) \). The release energy is obtained by setting the confinement potentials \( V_{ext}^{b,f} \) in eq. (4) to zero. This quantity can be measured via time-of-flight experiments.

At low temperature the thermal component \( n_{nc} \) can be safely neglected in the right hand side of equations (1) and (3). Similarly, when the fermionic density \( n_f \) is much smaller than the density \( n_c \) of the Bose condensate, its contribution in the right hand side of the same equations can be dropped. This is valid, for example, if the interaction strengths \( g_{ff} \) and \( g_{bb} \) have comparable size and if the trapping potential \( V_{ext}^b \) is not too stiff with respect to \( V_{ext}^f \). In this case the density profile of the condensate is not affected by the interaction with the fermions and the effective potential felt by the fermions takes the simplified form:

\[ V_{eff}^{f}(r) = \begin{cases} 
\frac{1}{2} m_f \omega_f^2 (1 - \gamma) r^2 + \frac{g_{bf}}{g_{bb}} \mu_b & \text{for } r < R_b \\
\frac{1}{2} m_f \omega_f^2 r^2 & \text{for } r \geq R_b 
\end{cases} \]
where

\[ \gamma = \frac{g_f m \omega_f^2}{g_h m \omega_f^2} \quad (8) \]

and \( R_0 = \left(2\mu_b/m\omega_f^2\right)^{1/2} \) is the radius of the condensate cloud. The potential \( \gamma \) depends on temperature through the boson chemical potential \( \mu_b \), which determines the radius \( R_0 \). Full numerical calculations, including the contribution of the thermal Bose and Fermi components, show that this simplified model (hereafter called the double-parabola model) describes very well the main features of the system below the critical temperature for Bose-Einstein condensation.

In the double-parabola model, if the parameter \( \gamma \) in eq. (8) is smaller than unity, the potential felt by the fermions has its minimum in the center of the trap. In this situation two limiting cases can be envisaged by comparing \( R_0 \) with the radius of the Fermi cloud. This is approximatively given by the Fermi radius \( \rho_0 \approx \hbar^2/(m\omega_f) \), where \( E_F = (6N_f)^{1/3}\hbar\omega_f \) is the Fermi energy. In the limit \( R_0 \ll R_F \) the number of bosons is much smaller than the number of fermions and thus the interactions play a minor role. Instead, in the limit \( R_0 \gg R_F \) the fermionic cloud feels a harmonic trapping potential with a renormalized frequency \( \tilde{\omega}_f = \omega_f(1 - \gamma)^{1/2} \). Finally in the case \( \gamma > 1 \) the repulsive interaction with the bosons is stronger than the external potential. The effective potential \( \tilde{\omega}_f \) then exhibits a local maximum at the center of the trap.

### III. SCALING AND ROLE OF THE INTERACTIONS AT \( T = 0 \)

Let us begin our discussion in the framework of the double-parabola model introduced in the previous section. In the case \( \gamma < 1 \) we can give a simple approximate solution of the model by a variational minimization of the energy functional in eq. (8). At \( T = 0 \) this reads

\[ E(T = 0) = \frac{3}{5} \hbar^2 \left( \frac{6\pi^2}{2m_f} \right)^{2/3} \int n_f^{5/3}(r) d^3r + \int V_f^b(r)n_f(r) d^3r + \int V_f^b(r)n_f(r) d^3r + \frac{g_h b}{2} \int n_f^2(r) d^3r + g_{bf} \int n_f(r)n_f(r) d^3r. \quad (9) \]

The variational approach (see the details in the Appendix) explicitly shows that the relevant properties of the system depend on the various parameters of the model through two adimensional combinations, which are the parameter \( \gamma \) in eq. (8) and a parameter \( x \) given by

\[ x = \sqrt{\frac{R_0}{R_F}} = \sqrt{\frac{m_f \omega_f}{2m_h \omega_h} \left( \frac{15a_{bh}}{a_{ho}} \frac{N_b}{(6N_f)^{3/5}} \right)^{1/5}}. \quad (10) \]

At given \( \gamma \), the ratio of the sizes of the two clouds in the absence of interactions determines the deviation of the kinetic energy of the Fermi component from its ideal-gas value.

We have checked numerically that the scaling in these two variables is satisfied with good accuracy also by the full numerical solution of eqs. (8)-(10) at zero temperature for any value of \( \gamma \). The description of the system with only two scaling parameters instead of the eight original ones entering eqs. (8)-(10) represents a major simplification of the problem. In view of this property, in the following we shall present our discussion in terms of the scaling parameters \( x \) and \( \gamma \).

In fig. 4a we show a plot of the kinetic energy as a function of \( x \) at zero temperature for different values of \( \gamma < 1 \). As \( x \) increases, the kinetic energy of the fermions goes from its non-interacting value \( E_{kin} = 3N_f E_F/8 \) to the strong-coupling limit \( E_{kin} = E_{kin}^0(1 - \gamma)^{1/2} \). As a first result of our analysis we see from fig. 4a that there is a clear correspondence, for a fixed value of \( x \), between the value of the kinetic energy and the value of \( \gamma \). Therefore the sign and the strength of the ratio between the boson-fermion and boson-boson coupling constants could be inferred from a measurement of the fermion kinetic energy.

In the case \( \gamma > 1 \) the fermions are expelled from the center of the trap \( [13, 22] \) and form a shell around the bosons as \( N_b \) increases with respect to \( N_f \). In this case the kinetic energy of the fermions (fig. 4b) tends to zero when \( x \to \infty \).

For completeness we have also analyzed the behaviour of the mean square radius of the fermionic cloud as a function of \( x \). For \( \gamma < 1 \) the asymptotic value at large \( x \) is larger (smaller) than in the ideal case for \( \gamma > 0(< 0) \) (see fig. 5a). For \( \gamma > 1 \) the mean square radius increases indefinitely with increasing \( x \) (fig. 5b). These behaviours are immediately understood in terms of the behaviour of the kinetic energy shown in fig. 4.
IV. THE ROLE OF TEMPERATURE

Let us finally examine the temperature dependence of the kinetic energy of the Fermi gas. To this purpose we have solved self-consistently the full set of eqs. (1-5). Of course, in the classical regime the kinetic energy is insensitive to interactions. As quantum degeneracy sets in at $T < T_F$, where $T_F = E_F/K_B$ is the Fermi temperature, deviations from the classical value $3N_f K_B T/2$ become apparent. We show in fig. 4 the predicted behaviour for a given choice of the parameters of the mixture. The role of the interactions decreases as temperature increases. This can also be seen in fig. 5 where we plot the kinetic energy as a function of $x$ for a choice of different temperatures.

The scaling behaviour described in sec. 11 is less accurate at finite temperature. This is easily understood from the fact that the approximations leading to eq. (6) become less justified as temperature increases.

V. CONCLUSIONS

We have presented a broad study of the kinetic energy of the fermionic component in a mixture of bosons and fermions in the so-called Thomas-Fermi regime $(N_b a_{bb}/a_{ho} \gg 1)$. We have shown that at zero temperature the kinetic energy, as well as the mean square radius of the Fermi component, exhibit an important scaling behaviour in the minimization of the energy functional (9) within a restricted class of functions.

In particular, we have found that the shift of the fermionic kinetic energy due to the interactions becomes sizeable at appreciable values of the parameter $x$ measuring the relative radii of the two clouds. This effect could be used to infer the sign of the boson-fermion scattering length from measurements of the fermion kinetic energy.

Finally, the role of temperature has been investigated within the self-consistent numerical solution of the full set of equations for the coupled boson-fermion mixture and the interplay between thermal and interaction effects on the kinetic energy has been demonstrated.

This work is supported by the Istituto Nazionale per la Fisica della Materia through the Advanced Research Project on BEC. One of us (L.V.) acknowledges the hospitality of the Scuola Normale Superiore di Pisa during part of this work.

APPENDIX A: VARIATIONAL MODEL

The scaling behaviour discussed in section 11 can be explicitly predicted by a variational approach which turns out to be very accurate in reproducing the numerical results at $T = 0$ in the case $\gamma < 1$. The variational method is based on the minimization of the energy functional (5) within a restricted class of functions.

For $\gamma < 1$ it is convenient to describe the fermionic cloud as if it were embedded in an effective potential $V_{var}(r) = \frac{1}{2} m_f \omega_{var}^2 r^2$, where the frequency $\omega_{var}$ is a variational parameter. The corresponding fermionic density profile is $n_f(r) = \frac{1}{(2\pi^2)(2m_f/\hbar^2)^{3/2}} \left( E_{Fvar}^2 - m_f \omega_{var}^2 r^2/2 \right)^{3/2}$ and the expression for the variational energy functional takes the form

$$ E_{var} = E_{kin} + E_{ho} + E_{int} = \frac{3}{8} N_f E_F \frac{\omega_{var}}{\omega_f} + \frac{3}{8} N_f E_F \frac{\omega_f}{\omega_{var}} + \frac{g_{bf}}{g_{bb}} \int \min(R_{Fvar}^2, R_0) \frac{1}{6\pi^2} \left( \frac{2m_f}{\hbar^2} \right)^{3/2} \left( E_{Fvar}^2 - \frac{1}{2} m_f \omega_{var}^2 r^2 \right)^{3/2} \left( \mu_b - \frac{1}{2} m_b \omega_{bvar}^2 \right) d^3 r. \quad (A1) $$

Here $E_{Fvar}^2 = (6N_f)^{1/3} \hbar \omega_{var}$ and $R_{Fvar}^2 = (2E_{Fvar}^2/m_f \omega_{var}^2)^{1/2}$ are the the Fermi energy and the Fermi radius calculated with the frequency $\omega_{var}$. The bosons are described by the Thomas-Fermi inverted parabola $n_b(r) = g_{bb}^{-1}(\mu_b - m_b \omega_{bvar}^2 r^2/2)$ with $\mu_b = \hbar \omega_b (15N_b a_{bb}/a_{ho})^{2/3}/2$.

The integral in eq. (A1) can be carried out analytically, with the result

$$ E_{var}(x, \gamma, \alpha) = \frac{3}{8} N_f E_F \times \begin{cases} \frac{\alpha^2}{x^2} + \frac{x^2}{\alpha^2} + \frac{\alpha^2}{x^2} P(\alpha) & \text{for } \alpha < 1 \\ \frac{\alpha^2}{x^2} + \frac{x^2}{\alpha^2} + \gamma \frac{\alpha^2}{x^2} \left( -1 + \frac{8}{3} \alpha^2 \right) & \text{for } \alpha \geq 1 \end{cases} \quad (A2) $$
where $\alpha^2 = x^2 \omega_{var}/\omega_f$ and

$$P(\alpha) = \frac{2}{9\pi} \left[ \alpha \sqrt{1 - \alpha^2} (9 - 18\alpha^2 + 40\alpha^4 - 16\alpha^6) + 3(-3 + 8\alpha^2) \arcsin(\alpha) \right], \quad (A3)$$

$$x = \sqrt{\frac{m_f \omega_f}{2m_b \omega_b}} \left( 15 \frac{a_{bb}}{a_{ho} N_b} \frac{N_b}{6N_f} \right)^{1/5}. \quad (A4)$$

The condition $\partial E_{var}/\partial \alpha = 0$ determines the value of $\alpha$ and hence of $\omega_{var}$. This equation has to be solved numerically, except for $\alpha \geq 1$ where the model gives the result $\omega_{var} = \bar{\omega}_f$.

The expression (A2) allows an explicit identification of the scaling variables introduced in sec. III. In fact, the quantity $E_{var}/N_f E_F$ at its minimum depends only on $x$ and $\gamma$.

Of course the variational estimate gives an upper bound for the total energy. This bound is very close to the value obtained by solving the Schrödinger equation with the potential (7). Typical deviations are less than 1 % of the energy.
