Certain well known quantum Hall states — including the Laughlin states, the Moore-Read Pfaffian, and the Read-Rezayi Parafermion states — can be defined as the unique lowest degree symmetric analytic function that vanishes as at least \( p \) powers as some number \( (g+1) \) of particles approach the same point. Analogously, these same quantum Hall states can be generated as the exact highest density zero energy state of simple angular momentum projection operators. Following this theme we determine the highest density zero energy state for many other values of \( p \) and \( g \).

I. INTRODUCTION

For two dimensional electron systems in very high magnetic fields, the kinetic energy becomes fully quenched, electrons become restricted to the lowest Landau level (LLL), and the effective Hamiltonian is reduced to the potential energy of the electron-electron interaction\(^8\). While naive intuition might suggest that a Hamiltonian with only a potential energy would result in a crystalline ground state, the analytic structure of the lowest Landau level puts enormous restrictions on the type of wavefunctions that can exist. It is this structure that is responsible for all the richness of the fractional quantum Hall effect. In Laughlin’s original explanation of the fractional quantum Hall effect\(^7\), he noticed that, due to the LLL analytic structure, his trial state could be completely defined by stating that the many particle wavefunction must vanish as a particular power of the distance between two electrons. In particular, for the Laughlin \( \nu = 1/m \) state, the wavefunction vanishes as \((z_1 - z_2)^m\) as particles with position \( z_1 \) and \( z_2 \) approach each other. The highest density wavefunction with this property is precisely the Laughlin state. It was discovered soon thereafter that these Laughlin wavefunctions were in fact the exact unique highest density zero-energy ground state of particles interacting with particularly simple short range model potentials\(^1\) that amount to projection Hamiltonians. In this paper, we intend to focus on these two related issues — the manner in which wavefunctions vanish, and the existence of simple model projection Hamiltonians.

To be more explicit, let us define \( L_2 \) to be the relative angular momentum of two particles. For electrons (which are fermions), \( L_2 \) must always be odd and the minimum value of \( L_2 \) in the LLL is given by \( L_2^{\text{min}} = 1 \). For bosons in a magnetic field (or rotating bose condensates, which can be mapped to bosons in a magnetic field\(^6\)), \( L_2 \) must be even and \( L_2^{\text{min}} = 0 \). We can then define a projection operator \( P^g_p \) with \( p \) to project out any state where any two particles have relative angular momentum less than \( L_2^{\text{min}} + p \). In the Lowest Landau level, this projection operator is precisely the above mentioned Hamiltonian that gives the Laughlin \( \nu = 1/(L_2^{\text{min}} + p) \) state as its ground state when \( p \) is even. In other words, this projection operator, when used as a Hamiltonian, gives positive energy to any situation where the wavefunction vanishes as \((z_1 - z_2)^m\) with \( m < L_2^{\text{min}} + p \), leaving the Laughlin state as the unique highest density zero energy (ground) state. Note that for \( p \) odd, the wavefunction cannot vanish as \( p \) powers, so \( P^g_p \) has the same effect as \( P^g_{p+1} \) in that both forbid relative angular momentum of \( p - 1 \) or less.

Another very interesting set of trial wavefunctions have also been studied that follow very much in this spirit. The Read-Rezayi \( Z_g \) parafermionic wavefunctions\(^2\) are the unique exact highest density zero energy (ground) state of simple \( (g+1) \) body interactions. Correspondingly, these wavefunctions can be completely defined by specifying the manner in which the wavefunctions vanish as \( g+1 \) particles come to the same point. The Moore-Read Pfaffian state, which is thought to be the ground state wavefunction for the observed \( \nu = 5/2 \) plateau\(^6\), is precisely the \( g = 2 \) member of this series. In addition, the particle hole conjugate of the \( g = 3 \) Read-Rezayi state has been proposed to be a candidate for the observed \( \nu = 12/5 \) fractional quantum Hall state\(^6\). Finally, we note that the \( g = 1 \) element of this series is just the Laughlin state with \( p = 1 \) or \( p = 2 \).

Analogously to our above construction for the Laughlin series, we may define \( L_{g+1} \) to be the relative angular momentum of a cluster of \( g+1 \) particles. It can be shown (and we will show below) that for electrons in the LLL, the minimal value of \( L_{g+1} \) is given by \( L_{g+1}^{\text{min}} = g(g+1)/2 \). For bosons, the minimal value would be \( L_{g+1}^{\text{min}} = 0 \). Symmetry dictates (as shown in appendix A) that \( L_{g+1} = L_{g+1}^{\text{min}} + 1 \) cannot occur, although any other value of \( L_{g+1} \geq L_{g+1}^{\text{min}} \) can occur for \( g > 1 \) (and \( L_2 \) must be even or odd for bosons or fermions respectively). Again we define \( P^g_{g+1} \) to be a projection operator that projects out any state where any cluster of \( g+1 \) particles has relative...
angular momentum \( L_{g+1} < L_{g+1}^{\text{min}} + p \). The Read-Rezai state can then be obtained from using the projection operator \( P^2_{g+1} \) as a Hamiltonian in the lowest Landau level. Note that since \( L_{g+1} = L_{g+1}^{\text{min}} + 1 \) is not allowed, the effect of \( P^1_{g+1} \) and \( P^2_{g+1} \) are both the same in that they give nonzero energy to states where any cluster has relative angular momentum \( L_{g+1} = L_{g+1}^{\text{min}} \). In this work we will consider the obvious generalization of the Read-Rezai construction, taking the Hamiltonian in the LLL to be given by the projection operator \( P^0_{g+1} \) for general \( g \) and \( p \).

The general restriction that the minimum relative angular momentum of \( g+1 \) particles be \( L_{g+1} \geq L_{g+1}^{\text{min}} + p \) can be expressed in terms of how the wavefunction vanishes as \( g+1 \) particles approach each other. For bosons, where \( L_{g+1}^{\text{min}} = 0 \), the wavefunction does not need to vanish as \( g \) particles approach a given position \( \tilde{z} \) but as the \( g+1 \text{st} \) particle arrives, the wavefunction must vanish as \( (z_{g+1} - \tilde{z})^p \). The situation for fermions, however, is a bit more complicated, and will be discussed in section \( \text{[XX]} \) below.

The purpose of this paper is to determine the highest density zero energy state of the proposed Hamiltonian \( P^0_{g+1} \) which is a natural generalization of the Laughlin, Moore-Read, Read-Rezai, Haffnian and Gaffnian Hamiltonians. While we will not find a solution for arbitrary \( g \) and \( p \), we will be able to find a solution for many values of \( g \) and \( p \) that have not been previously discussed. We note that in addition to the Laughlin states \( (g=1) \) and the Read-Rezai states \( (p=1 \text{ or } p=2) \), the ground state of the \( g=2 \) and \( p=4 \) case, know as the “Haffnian” has been previously discussed by Green. In addition, the ground state of \( g=2 \) and \( p=3 \) has been dubbed the “Gaffnian”, and is discussed in depth in a companion paper by the current authors. (The name “Gaffnian” is an alpha-phonetic interpolation between the \( p=2 \) \( \text{pFaffian} \) and the \( p=4 \) Haffnian).

The outline of this paper is as follows. We begin by fixing notations and conventions in section \( \text{[I]} \). In section \( \text{[II]} \) we define the concept of a ”proper” cluster wavefunction which is crucial to our arguments. Through much of this paper we focus on boson wavefunctions. In section \( \text{[III]} \) we start filling out a table as to the highest density ground state of the Hamiltonian \( P^0_{g+1} \). Although we do not fill in all possible values of \( p \) and \( g \), we do determine quite a few (results are given in Table I). In section \( \text{[IV]} \) we discuss attaching jastrow factors to the resulting wavefunctions, and in particular the fermionic analogues of these wavefunctions. We find that the structure of the table for fermions and bosons is identical.

**A. Preliminaries**

We will always represent a particle’s coordinate as an analytic variable \( z \). On the plane \( z = x + iy \) is simply the complex representation of the particle position \( \mathbf{r} \). On the sphere, \( z \) is the stereographic projection of the position on the sphere of radius \( R \) to the plane. All distances will be measured in units of the magnetic length. In symmetric gauge, single particle lowest Landau level wavefunctions \( \psi(z) \) are given as analytic functions \( \psi(z) \) times a measure \( \mu(z) \).

\[ \psi(z) = \mu(z) \psi(z) \]  

On the disk the measure is

\[ \mu(z) = e^{-|z|^2/4} \]  

whereas on the sphere (with stereographic projection) the measure is

\[ \mu(z) = \frac{1}{[1 + |z|^2/(4R^2)]^{N_\phi/2}} \]  

with \( N_\phi \) being the total number of flux penetrating the sphere. On the sphere the degree of the polynomial \( \psi(z) \) ranges from \( z^0 \) to \( z^{N_\phi} \) giving a complete basis of the \( N_\phi + 1 \) states of the LLL. On the disk, the degree of \( \psi \) can be arbitrary.

We will write multiparticle wavefunctions \( \Psi \) for \( N \) particles in the lowest Landau level as an analytic functions \( \psi \) of \( N \) variables times the measure \( \mu \)

\[ \Psi(z_1, \ldots, z_N) = \psi(z_1, \ldots, z_N) \mu(z_1, \ldots, z_N) \]  

with

\[ \mu(z_1, \ldots, z_N) = \prod_{i=1}^{N} \mu(z_i) \]  

On the sphere, the polynomial \( \psi \) cannot be of degree greater than \( N_\phi \) in any variable \( z_i \).

A quantum Hall ground state wavefunction will be a translationally, rotationally invariant quantum liquid. The restriction we impose on \( \psi \) is that it must be a translationally invariant homogeneous polynomial of degree \( N_\phi \). On the sphere, the degree \( N_\phi \) is just the number of flux through the sphere. Conversely, given a (translationally and rotationally invariant) quantum Hall wavefunction on a sphere, the flux \( N_\phi \) can be identified as the highest power of \( z_i \) that occurs. We note that so long as our interaction in the lowest Landau level is time reversal invariant, we can (and will) choose the the polynomial \( \psi \) with real coefficients of all terms. As the size of a system is extrapolated to the thermodynamic limit, we have the relation

\[ N_\phi = \frac{1}{\nu} N - S \]  

with \( \nu \) the filling fraction, and \( S \) is known as the “shift”. We note that on a torus geometry there is typically no shift.

For a bosonic wavefunction \( \psi \) must be symmetric in its arguments, whereas for a fermionic wavefunction it must be antisymmetric in its arguments. A well known theorem tells us that any antisymmetric function can be
written as a single Vandermonde determinant times a
bosonic function. In this way we can generally write
\[ \psi_{\text{fermion}}(z_1, \ldots, z_N) = J \psi_{\text{boson}}(z_1, \ldots, z_N) \] (7)
where
\[ J = \prod_{i<j} (z_i - z_j) \] (8)
Using this relation, the translation from bosons to
fermions is quite easy. It is easy to see that the filling
fraction \( \nu_f \) for fermions is related to that of the corre-
sponding filling fraction for bosons \( \nu_b \) via
\[ \nu_f = \frac{\nu_b}{\nu_b + 1} \] (9)
Throughout much of this paper we will be focused on
bosonic wavefunctions for clarity. We will return to the
issue of fermionic wavefunctions briefly in section IV be-
low.

II. PROPER CLUSTER WAVEFUNCTIONS

We begin by focusing on bosonic wavefunctions. A
\( g \)-cluster wavefunction \( \psi \) will be defined by the analytic
manner in which the wavefunction vanishes when the \( g+1 \)
particles are brought to the same point \( \tilde{z} \). Generally, we
will write this \( g+1 \) particle limiting behavior
\[ \lim_{z_1, \ldots, z_{g+1} \rightarrow \tilde{z}} \psi(z_1, \ldots, z_N) \sim f(z_1, \ldots, z_{g+1}) \tilde{\psi}(\tilde{z}; z_{g+2} \ldots z_N) \] (10)
The wavefunction \( \psi \) must vanish in this manner as any
\( g+1 \)th particle approaches. We can thus write that
\[ \psi(\tilde{z}, \tilde{z}, \ldots, \tilde{z}, z_{g+1}, z_{g+2}, \ldots, z_N) \sim \left[ \prod_{i=g+1}^{N} (\tilde{z} - z_i)^p \right] \tilde{\psi}_1(\tilde{z}; z_{g+1} \ldots z_N) \] (12)
where \( \tilde{\psi}_1 \) is a wavefunction satisfying Eq. (10) for the re-
mainion \( N-g \) particles (and may have some dependence on \( \tilde{z} \) as well).

Using this recursion relation, it is easy to calculate the
filling fraction and shift of this wavefunction. We claim
that for a proper \( f \) of degree \( p \) (i.e., one that does not
vanish when \( g \) of its arguments come to the same point),
the densest wavefunction satisfying condition (10) occurs
at flux \( N_0 = pN/g - p \) so long as \( N \) is a multiple of \( g \).
Thus, this wavefunction has filling fraction and shift
\[ \nu = g/p \quad S = p. \] (13)
To see this result more explicitly, we imagine bringing
together particles into groups of \( g \) particles and using the
above recursion relation (Eq. 12) a total of \( N/g - 1 \)
times. Let us put the first cluster of particles at position
\( \tilde{z}_1 \), the second at position \( \tilde{z}_2 \) and so forth until we have
grouped the \( N/g - 1 \)th group at position \( \tilde{z}_{N/g-1} \). The last \( g \) particles we leave ungrouped. Using the recursion
law we obtain a wavefunction
where $\chi_{N/g-1}$ is not allowed to vanish as any of its $g$ remaining arguments $z_j$ coalesce. The highest density wavefunction satisfying the limiting behavior Eq. 10 (i.e., the quantum Hall state with no quasiholes) could thus have $\chi$ being unity. Examining the degree of this polynomial with respect to the position of $z_N$ we see that it is of degree $p(N/g - 1)$. Thus, we have a wavefunction corresponding to flux $N_g = p(N/g - 1) = (p/g)N - p$ which indicates $\nu = g/p$ and $\mathcal{S}$ as $p$ as claimed. For each proper function $f$, there exists at most one corresponding quantum Hall ground state wavefunction which would be the maximum density translationally invariant wavefunction for which Eq. 10 is always obeyed. Of course, just because we have constructed an appropriate $f$ for $g+1$ particles, it is not clear how one can construct a wavefunction with a large number of particles $N$ such that Eq. 10 is obeyed as any combination of $g+1$ particles approach each other. In essence we are asking how to “sew” together many functions $f$ to form a macroscopic wavefunction. Sometimes such macroscopic wavefunction exists. For example, in Appendix B it is shown that for odd $pg$ no such macroscopic wavefunction exists. We note, however, that many proper cluster wavefunctions are already known. The $Z_g$ Read-Rezayi states, for example are proposer $p = 2$ states for any $g$ (including the Pfaffian, which is $g = 2, p = 2$). The Laughlin states are proper for $g = 1$ with even $p$. The Haffnian state is proper with $g = 2, p = 4$ case, and recently the current authors have studied the “Gaffnian” state, which is proper with $g = 2, p = 3$. Further, in the next section we will not need to know that any more proper wavefunctions actually exist. What is important is that if they exist, we know what their filling fractions are.

III. MAIN RESULTS

We now examine possible pair combinations of $g$ and $p$ and ask what the ground state is of the projection Hamiltonian $P_{g+1}^p$. Again we will consider here only the case of bosons. These results are summarized in Table I. In many of the examples below, we will use the same type of reasoning: A wavefunction that vanishes as $g+1$ particles come together must be either improper or proper (either it does or does not vanish as only $g$ particles come together). We determine the densest possible zero energy state for both of the two possibilities and then compare these two with each other to find the densest of all possible zero energy states.

- $g = 1$: the Laughlin series:

The Hamiltonian $P_{g+1}^p$ gives positive energy to any pair of particles with relative angular momentum less than $p$. This leaves the highest density zero energy ground state being the $\nu = 1/p$ bosonic Laughlin state for even $p$. For odd $p$, the Hamiltonian does not allow pairs to have relative angular momentum $p - 1$ so the highest ground zero energy ground state is the $1/(p+1)$ bosonic Laughlin state.

- $p = 1, p = 2$: the Read-Rezayi series:

As discussed in the introduction, it has been shown that projecting out the minimal angular momentum of $g+1$ particles (projecting out $L_{g+1} = 0$ for bosons) results in the $Z_g$ Read-Rezayi state. Since $L_{g+1} \neq 0$ as shown in Appendix A we we conclude that the highest density zero energy state of both $P_{g+1}^p$ and $P_{g+1}^{p-1}$ is the $Z_g$ Read-Rezayi state whose filling fraction is $\nu = g/2$ for bosons. Note that this includes $g = 2$ with $p = 1, 2$ which gives the Moore-Read state (which is just the $g = 2$ member of the Read-Rezayi series).

- $g = 2, p = 3$ Gaffnian:

The case $g = 2, p = 3$ give the Gaffnian state. We need not go into much detail as to the physics of this state but to indicate that such a proper cluster wavefunction at $\nu = 2/3$ for bosons exists. Detailed discussion of this wavefunction is given in Ref. 11. For completeness, we now consider also the possibility that the ground state is not a proper cluster wavefunction, but rather an “improper” wavefunction (meaning it vanishes as only two particles come together). However, we know that the highest density bosonic wavefunction that vanishes when two come together is the Laughlin $\nu = 1/2$ state, which is not as dense as the Gaffnian.

- $g = 2, p = 4$ Haffnian:

Similarly, the $g = 2, p = 4$ case give the Haffnian. Again, this is a proper cluster wavefunction for $\nu = 1/2$ for bosons has been previously discussed in detail. Again, we consider the possibility that the highest density state is an improper wavefunction. Indeed, the highest density improper wavefunction is the Laughlin $\nu = 1/2$ state which which vanishes even faster than the Haffnian as
3 particles come to the same point (so it is also a zero energy state of $P_3^6$). Comparing these two possibilities, the Haffnian is considered the ground since it has a shift of $S = 4$ whereas the Laughlin $\nu = 1/2$ state has a shift of $S = 2$. Thus the filling fraction of the Haffnian is slightly greater by an amount order $1/N$ (with $N$ the number of particles). Note, however, on a torus geometry, where there is no shift, the density of these two states is the same (and indeed, there are many other states with the same density too\cite{footnote}).

- **The $g = 2$ series for $p = 5, 6$:**

  Let us start by considering the cases of $g = 2$ and $p = 5, 6$. Suppose the highest density ground state is a proper cluster wavefunction. In this case, the filling fractions in these two cases would be $\nu = 2/5$ and $\nu = 2/6$ respectively (See Eq. \[13\]). We now consider the possibility that the ground state is improper. The highest density improper state (ie, state that vanishes as two particles come together) is the Laughlin $\nu = 1/2$ state. This is denser than the proper possibilities. Furthermore the Laughlin $\nu = 1/2$ state is also a zero energy state of the relevant Hamiltonians $P_5^6$ and $P_6^6$ since the Laughlin state vanishes as 6 powers when three particles come together. Thus we conclude that the Laughlin $\nu = 1/2$ state is the densest zero energy state of these Hamiltonians.

- **The Periodic $g = 2$ series:**

  For $p > 6$, we proceed similarly. If the highest density ground state is proper, the filling fraction is $\nu = g/p$. Now suppose the ground state is improper. In this case, the wavefunction must vanish as two particles come together. It is well known that any symmetric wavefunction $\psi$ that vanishes as two particles come together can be written as two Jastrow factors (See Eq. \[5\]) times another symmetric wavefunction $\psi'$

  $$\psi(z_1, \ldots, z_N) = J^2 \psi'(z_1, \ldots, z_N)$$

  (Compare Eq. \[7\]). The filling fraction $\nu$ of $\psi$ is related to the filling fraction $\nu'$ of $\psi'$ via

  $$\nu = \frac{\nu'}{2 + \nu'}$$

  This is analogous to the usual composite fermion transformation (compare also Eq. \[9\]). Further, if $\psi$ vanishes as $p$ powers when 3 particles come together, then $\psi'$ vanishes as $p' = p - 6$ powers (the 6 being from the Jastrow factors). Thus, if $\psi$ is improper with $g = 2$ we are equivalently looking for a wavefunction $\psi'$ that vanishes at least as $p - 6$ powers when 3 particles come together. Thus, we discover that the highest density improper wavefunction for $6 < p \leq 12$ is just two Jastrow factors times the ground state of $P_2^{p-6}$. For $p \leq 6$ we have already calculated the ground state of $P_2^p$ (i.e., $p = 1, 2$ is Pfaffian, $p = 3$ is Gaffnian, $p = 4$ is Haffnian, and $p = 5, 6$ is Laughlin), thus we know the highest density improper ground state of $P_2^p$ for $6 < p \leq 12$. It is easy to verify that the filling fraction of this improper state is greater than the $\nu = g/p$ proper possibility. For $12 < p \leq 18$ we can repeat the argument and find that it is again the same series but with 4 Jastrow factors and so forth.

  - **Read-Rezayi Series again for $p = 3, 4$:**

    We now consider the case of $p = 3, 4$ for arbitrary $g$. If the highest density state is a proper $g$-cluster wavefunction then the filling fraction will be $\nu = g/p$ as usual. If the wavefunction is improper, then it must vanish as only $g$ particles come together. But we already know that the highest density state that vanishes as $g$ particles come together is the $Z_{g-1}$ Read-Rezayi state whose filling fraction is $\nu = (g-1)/2$. Furthermore, as shown in Appendix C the $Z_{g-1}$ Read-Rezayi wavefunction vanishes as 4 powers when $g + 1$ particles come together (for $g > 1$). Thus, so long as $(g-1)/2 > g/p$, the Read-Rezayi $Z_{g-1}$ state is the highest density zero energy state of $P_{g+1}^4$ and $P_{g+1}^4$. Note that this inequality is satisfied for $g > 2, p = 4$ and $g > 3, p = 3$.

  - **The $g = 3, p = 3$ Pfaffian:**

    For the $g = 3, p = 3$ case, the above inequality $(g-1)/2 > g/p)$ is instead an equality. Thus, this case is marginal. Here, the putative proper state occurs at $\nu = 1$, and the improper state is the $Z_2$ Read-Rezayi state (the Moore-Read Pfaffian) which is also $\nu = 1$. The shift of the Pfaffian is $S = 2$, where as the shift of a $p = 3$ proper state should be $S = 3$. Thus, we would expect that the proper state is denser. However, in appendix D we show that, by symmetry, no proper state can exist for $pg$ odd as we have in this case. So there is no wavefunction at $\nu = 1$ with shift $S = 3$. Thus, the Pfaffian is the densest possible zero energy state of $P_3^3$. In this case, we do not eliminate the possibility that another zero energy state may exist with exactly this filling fraction (and perhaps the same shift). An otherwise “proper” state where a term has been added to fix the symmetry could occur. Indeed, exact diagonalization on the torus has revealed at least one other zero energy state at the same filling fraction.

  - **The $g = 3, p = 5, 6$ States: Gaffnian Conjecture:**

    We again consider first the possibility that the ground state of $P_3^5$ and $P_3^6$ are proper. These wavefunctions would have filling fractions 3/5 and 3/6 respectively. The other possibility is that the highest density ground state is improper (ie, it vanishes as only three particles come together). Now consider the Gaffnian wavefunction. This has filling fraction 2/3, and from the explicit form of the wavefunction given in Ref. II, it can be seen that it vanishes as 6 powers when 4 particles come together. Hence, the highest density ground states of $P_3^5$ and $P_3^6$ must be improper. However, there could be another (improper)
zero energy state that also vanishes as 3 particles come together which is higher density than the Gaffnian. We conjecture that the Gaffnian is indeed the highest density zero energy state in these cases. However, we have not been able to prove this conjecture.

| $g$ | $p = 1, 2$ | $p = 3$ | $p = 4$ | $p = 5$ | $p = 6$ | $p = 7$ | $p = 8$ | $p = 9$ | $p = 10$ | $p = 11$ | $p = 12$ | $p = 13$ |
|-----|------------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|---------|

Table I: Highest density zero energy ground state of bosons with Hamiltonian $P^g_{g+1}$. The entries in this table are “Name of state” followed by filling fraction. Abbreviations are $P$ = Pfaffian; $G$= Gaffnian; $H$=Haffnian; $J^n$ = Jastrow Factor to the $n^{th}$ power; $R_n = Z_n$ Read-Rezayi state. So for example, the $g = 2$, $p = 9$ slot has $G J^2 : \frac{5}{4}$ which means the wavefunction is the gaffnian times 2 Jastrow factors which occurs at filling fraction 2/7. Note that Laughlin states are listed only as $J^n$. An asterisk indicates that the state is “marginal” in that there are other states competing with this state that differ at most by a finite shift. For fermions the structure of the table would be identical except that the filling fractions would be related to these bosonic filling fractions by Eq. [11].

### IV. ADDING JASTROW FACTORS

So far we have only considered bosonic wavefunctions. Given any bosonic wavefunction $\psi_0$ such as any of those discussed above, we can construct wavefunctions

$$\psi = \psi_0 \prod_{i<j} (z_i - z_j)^M = J^M \psi_0$$  \hspace{1cm} (17)

For even $M$ this would then be another bosonic wavefunction, whereas for odd $M$ this would be a fermionic wavefunction. Of particular interest is the $M = 1$ case which was also discussed above in Eq. [7]. Here, more generally, the filling fraction $\nu$ of $\psi$ in terms of the filling fraction $\nu_0$ of $\psi_0$ as

$$\nu = \frac{\nu_0}{M + \nu_0}$$  \hspace{1cm} (18)

There is, of course, a one to one mapping between the possible space of wavefunctions $\psi_0$ and those in the space of $\psi$. The defining limiting behavior of the wavefunction $\psi$ is now given by (Compare Eq. [11]).

$$\lim_{z_1, \ldots, z_{g+1} \to z} \psi(z_1, \ldots, z_N) \sim f(z_1, \ldots, z_{g+1}) \left[ \prod_{1 \leq i < j \leq g+1} (z_i - z_j)^M \right] \tilde{\psi}_0(\tilde{z} : z_{g+2} \ldots z_N)$$  \hspace{1cm} (19)

when $g + 1$ particles come together and

$$\lim_{z_1, \ldots, z_k \to \tilde{z}} \psi(z_1, \ldots, z_N) \sim \left[ \prod_{1 \leq i < j \leq k} (z_i - z_j)^M \right] \tilde{\psi}_{0k}(\tilde{z} : z_{k+1} \ldots z_N)$$  \hspace{1cm} (20)

when $k < g + 1$ particles come together. In other words, the wavefunction vanishes as the Jastrow factor only
when less than \( g + 1 \) particles come together, and vanishes increasingly quickly (as defined by the function \( f \)) when \( g + 1 \) come together. Thus, if \( f \) vanishes as \( p \) powers when \( g + 1 \) particles come together, the wavefunction \( \psi \) vanishes as \( Mg(g+1)/2+p \) powers when \( g + 1 \) particles come together.

Enforcing the presence of Jastrow factors is a well known procedure. For bosons, \( M = 2 \) is obtained by forbidding any two particles to have relative angular momentum of zero. In other words, adding a term \( P^2_2 \) to the Hamiltonian will assure that any zero energy wavefunction contains an overall \( M = 2 \) Jastrow factor. This term, \( P^2_2 \) is usually known as a \( V_0 \) interaction since it projects out pairs of particles with relative angular momentum zero. Similarly, to enforce an \( M = 4 \) Jastrow factor, one adds \( P^4_2 \) to the Hamiltonian (In the usually nomenclature this is a \( V_3 \) term and a \( V_5 \) term). So, for example, if a given wavefunction \( \psi_0 \) is the highest density zero energy ground state of \( P^g_{g+1} \) then \( \psi = J^M \psi_0 \) should be the highest density zero energy ground state of

\[
P^M_2 + P^{M(g+1)/2+p}_{g+1}
\]

with \( M \) even. It is interesting to note that in cases listed in table I above, the term enforcing the Jastrow factors is not needed. For example, the highest density zero energy state of \( P^3_3 \) is the Gaffnian. Thus, choosing any even \( M \) we would expect that the highest density zero energy state of \( P^M_2 + P^{3M+p}_3 \) should be \( J^M \) times the Gaffnian. It is interesting, that in this particular case the highest density zero energy state of \( P^M_2 \) is already \( J^M \) times the Gaffnian without including the Jastrow forcing term \( P^M_2 \). This is an intriguing phenomenon, and we do not know if it is general.

We now return to the case of Fermions. As mentioned above in the introduction (See Eq. 4), any fermi wavefunction can be written as a boson wavefunction times a single Jastrow factor. Thus, by simply using a system of Fermions, an \( M = 1 \) Jastrow factor is automatically obtained. We also note that this immediately tells us that the minimum angular momentum of \( g + 1 \) fermions in the LLL is

\[
L^{\text{min: fermion}}_{g+1} = g(g+1)/2
\]

Since we have defined \( P^g_{g+1} \) to project out relative angular momenta \( L < L^{\text{min}} + p \), the table generated as the highest density zero energy state of \( P^g_{g+1} \) is the same for fermions as it is for bosons only the resulting fermion wavefunctions have an overall Jastrow factor attached (\( M = 1 \)).

To add further Jastrow factors to a Fermionic wavefunction, we follow the analogous scheme to the Bosonic case, projecting out any pairs of fermions with the minimal angular momenta. Thus, for Fermions, our operator \( P^2_2 \) is defined to project out any pair with minimum angular momentum less than \( L = L^{\text{min: fermion}}_2 + 2 = 3 \). Thus, a zero energy state of \( P^2_2 \) for fermions must have at least \( M = 3 \) Jastrow factors in the wavefunction. Conventionally such a term is known as a \( V_1 \) term of the Hamiltonian. Similarly, a zero energy state of \( P^2_2 \) for fermions must have at least \( M = 5 \) Jastrow factors in the wavefunction. Note that, by construction, this again follows the rule that the resulting wavefunctions will always be the bosonic analogue times a single Jastrow factor.

V. DISCUSSION

The wavefunctions we have constructed in this paper all stem from reasonably simple Hamiltonians, which involve projecting out clusters of particles with given angular momenta. The simplicity of this construction, is, of course, much of the attraction of our theory. It is interesting that the only fundamentally “new” state that has appeared on our table of states so far is the Gaffnian, which will be discussed in depth in a companion to this paper. It would be interesting to fill in the rest of Table I to see if any other new states might appear.

Some of the states that fit in our scheme are of course well known and well established to occur in nature. For example, the Laughlin states are certainly seen in the Lowest Landau level. Also among the states that fit in our construction is the Moore-Read Pfaffian, which is strongly thought to be the explanation of the plateau seen in the first excited Landau level at \( \nu = 2 + 1/2 \). In addition, there are several states in our scheme that seem likely to be seen in nature, although there remains some level of uncertainty. For example, There is some evidence that the the particle-hole conjugate of the \( g = 3 \) Read-Rezayi state is a good trial state for \( \nu = 2 + 2/5 \), which has been observed recently. A detailed discussion of the Gaffnian wavefunction is given in a companion to this paper. Although the Gaffnian has extremely high overlap with \( \nu = 2/5 \) there is reason to believe that the Gaffnian is a critical state rather than a phase.

It is interesting to note that in the Lowest landau level, most of the known physics appears to be outside of the general scheme set out in this paper. Instead, it appears that most of the states seen in the LLL are most easily explained within a composite fermion theory. In contrast to the current work, the composite fermion wavefunctions (with the exception of the Laughlin states) are not the exact ground state of any known simple Hamiltonian – even though they are extremely accurate wavefunctions for Coulomb (and similar) interactions in the LLL. There are also possibilities that some of these states might be observed in systems of cold atoms. Rotating Bose condensates can be thought of as Bosons in a magnetic field and thus (if sufficiently two dimensional) become quantum Hall systems. In cold atom systems, experimentalists have been extremely clever about designing Hamiltonians to have desired interactions. Indeed, a scheme has been devised which essentially generate exactly the type of \( g + 1 \)-particle interaction necessary to yield the Read-Rezayi cluster series. Another approach to generat-
ing the Pfaffian in cold atoms have also been proposed\cite{footnote1}, which does not rely on rotation.

Since the Hamiltonians we are proposing in this paper are relatively simple, we might hope that clever experimentalists will be able to devise systems in which these Hamiltonians are realized.

**APPENDIX A:** \( L_{g+1} \neq L_{g+1}^{\text{min}} + 1 \)

The statement that \( g+1 \) bosons have relative angular momentum \( p \) is equivalent to saying that as the particles all approach the same point, the wavefunction vanishes as a \( p^{th} \) degree polynomial \( f \) in the sense of Eq. 10. The function \( f \) must be a translationally invariant symmetric polynomial. We claim that no such polynomial exists of degree one. To see this we note that there is only a single symmetric polynomial in \( g+1 \) variable of degree one

\[
\sum_{i=1}^{g+1} z_i \tag{A1}
\]

and under translation \( z_i \rightarrow z_i + a \) this is not invariant. Thus we conclude that \( g+1 \) bosons cannot have relative angular momentum 1. Writing any fermion wavefunction as an overall Jastrow factor times a boson wavefunction (See Eq. 7) one can then show that generally \( L_{g+1} \) cannot be \( L_{g+1}^{\text{min}} + 1 \).

**APPENDIX B: ODD \( pg \) PROPER BOSON WAVEFUNCTIONS DO NOT EXIST**

Here, we claim that when both \( g \) and \( p \) are odd no macroscopic bosonic wavefunction exists with shift of \( p \) for that \( g \) and \( p \). To see this, we use the recursion relation Eq. 12 (which is true as long as the wavefunction does not vanish as \( g \) particles coalesce, ie, as long as it is proper) and group the particles into groups of \( g \) at positions \( \tilde{z}_i \). The wavefunction of the clustered super-particles is given by

\[
\psi = \prod_{i<j}(\tilde{z}_i - \tilde{z}_j)^{pg} \tag{B1}
\]

However, a cluster of \( g \)-bosons must remain a bosonic object (ie, the wavefunction is symmetric under interchange), whereas \( pg \) is odd. This tells us immediately that no such wavefunction can exist.

**APPENDIX C: THE READ-REZAYI WAVEFUNCTION**

As shown by Ref. 14, the bosonic Read-Rezayi wavefunction can be written by dividing the particles into \( g \) groups, giving Jastrow factors only between particles in the same group, and then symmetrizing over all choices of which particle is in which group. We will assume the total number of particles \( N \) is divisible by \( g \) and define the first group to be particles 1 \( \ldots \) \( N/g \), the second group to be \( N/g + 1 \ldots 2N/g \) and so forth. We thus write the \( Z_g \) Read-Rezayi bosonic wavefunction as

\[
\psi = S_N \left[ \prod_{0<i_1<i_2 \leq N/g} (z_{i_1} - z_{j_1})^2 \prod_{N/g<i_2<i_3 \leq 2N/g} (z_{i_2} - z_{j_2})^2 \ldots \prod_{(g-1)N/g<i_2<j_2 \leq N} (z_{i_g} - z_{j_g})^2 \right] \tag{C1}
\]

where \( S_N \) represents symmetrization over all particle coordinates. It is trivial to establish that the filling fraction is \( \nu = g/2 \) and the shift is \( S = 2 \). When \( g \) bosons come together, one can be in each group so the wavefunction does not vanish. When \( g+1 \) bosons come together, at least two of them must be in the same group and the wavefunction vanishes as \( p = 2 \) powers. Similarly when \( g+2 \) particles come together (for \( g > 1 \)), at least two groups have two bosons in them, meaning the wavefunction vanishes as \( p = 4 \) powers.
