Significantly enhancement of sunlight photocatalytic performance of ZnO by doping with transition metal oxides

Alfonso E. Ramírez¹², Marly Montero-Muñoz², Lizbeth L. López³, J. E. Ramos-Ibarra³, Jose A. H. Coaquira², Benoît Heinrichs⁴ & Carlos A. Péaz⁴

In this study we report the synthesis of ZnO and its doping with Transition Metal Oxides -TMO-, such as Cr₂O₃, MnO₂, FeO, CoO, NiO, Cu₂O and CuO. Various characterization techniques were employed to investigate the structural properties. The X-ray diffraction (XRD) data and Rietveld refinement confirmed the presence of TMO phases and that the ZnO structure was not affected by the doping with TMO which was corroborated using transmission Electron microscopy (TEM). Surface areas were low due to blockage of adsorption sites by particle aggregation. TMO doping concentration in the range of 3.7–5.1% was important to calculate the catalytic activity. The UV–Visible spectra showed the variation in the band gap of TMO/ZnO ranging from 3.45 to 2.46 eV. The surface catalyzed decomposition of H₂O₂ was used as the model reaction to examine the photocatalytic activity following the oxygen production and the systems were compared to bulk ZnO and commercial TiO₂-degussa (Aeroxide-P25). The results indicate that the introduction of TMO species increase significantly the photocatalytic activity. The sunlight photocatalytic performance in ZnO-doped was greater than bulk-ZnO and in the case of MnO₂, CoO, Cu₂O and CuO surpasses TiO₂ (P25-Degussa). This report opens up a new pathway to the design of high-performance materials used in photocatalytic degradation under visible light irradiation.

The importance of raising global awareness about how light-based technologies promote sustainable development and provide solutions to global challenges has been recognized by the United Nations¹ In the environmental field, light can play a vital role, because its combination with semiconductor materials it provides a great power for photodegradation². It is well known the use of semiconductors like TiO₂³ and ZnO for this purpose⁴. Likewise, it is known that the wide band gap of these metal oxides limits their use in the visible range⁵. Additionally, rapid recombination of hole-electrons pairs is another limitation of ZnO⁶.

Therefore, the development of new generation nanophotocatalysts is a challenge for improving their photocatalytic activity in visible light. In the case of ZnO its application has been limited due to its large band gap⁷, which can decrease the photocatalytic properties⁸. One strategy to enhance their performance and its use with a light source, is doping with different elements and/or its compounds⁹. In case of ZnO, doping with the noble metals where Ag is most reported¹⁰–¹³, but we can find reports for Pt¹⁴, Pt¹⁵ and Au¹⁶,¹⁷. Other elements that have received special attention correspond to the lanthanide series¹⁸ specifically Ce¹⁹,²⁰, Eu²¹, Gd²²,²³ and La²⁴. Others metals of d-type that are also studied include Fe²⁵, Ni²⁶,²⁷, Mn²⁸,²⁹, Co³⁰,³¹ and Cu³²–³⁴.

The surface catalyzed decomposition of H₂O₂ has been reported as useful, simple and inexpensive way to evaluate the catalytic activity on solids under UV–visible light irradiation³⁵–³⁷. In this work, we have used the surface photodecomposition of H₂O₂ to show that doping ZnO with transition metal oxides -TMO-, enhance the photocatalytic powder of ZnO. In the case of doping with MnO₂, Co₂O₃ and CuO, the resulting systems can become possible substitutes to most efficient commercial photocatalyst: Aeroxide TiO₂/P25. This new information can be utilized to the future design of materials for the photocatalytic degradation under visible light irradiation.

Results and discussion

Characterization. Zinc oxide phase corresponding to the wurtzite hexagonal structure (PDF 00–900–4179), with space group P63mc is the main phase as can be seen in Fig. 1. In addition to the ZnO main phase, reflections related to transition metal oxide dopant phase (see in the insets of Fig. 1) are determined. The following TMO phases were identified: CuO (PDF 00–901–6057), Cu2O (PDF 00–900–7497), CoO (PDF 00–591–0031), Cr2O3 (PDF 00–900–7442), Fe2O3 (PDF 00–901–6457), NiO (PDF 00.432–0493) and MnO2 (PDF 00–151–4237).

In order to determine additional information, the XRD patterns were analyzed using the Rietveld refinement method. It was determined that the doping with TMO did not affect the wurtzite structure of ZnO, since all characteristic reflections of ZnO phase were also obtained in the XRD pattern of TMO/ZnO samples. The lattice constants, unit cell volume and percentage of phases are listed in Table 1. In all of cases, the static structure factor of the wurtzite phase (c/a ~ 1.602) remains constant. It suggests that essentially no changes were determined in the lattice constants of the wurtzite phase, implying that the transition metal did not diffuse into the ZnO structure, in agreement with that reported in the literature. Otherwise, the diffusion could lead to the substitution of Zn ions by the transition metal ions and it could lead to changes in the lattice constants of the wurtzite structure, which is not observed.

TEM measurements were performed in order to get more information about the crystalline structure of the photocatalysts, mainly the particle size. Figure 2 shows the typical TEM images of the synthesized catalysts. Figure 2a shows the ZnO nanoparticles with a hexagonal structure and Fig. 2b presents ZnO powder modified with TMO.

As shown in Fig. 2a we can inferred the mean size of the ZnO nanoparticles, which is close to 47 ± 5 nm. In Fig. 2b is shown that the particles are in the nanoscale (approximately 50–60 nm in size) and reveals: (i) an increase in size, may be as a result of the TMO surface covering of ZnO nanoparticles and (ii) the conservation of hexagonal structure, indicating that the structure of ZnO is not notoriously affected by the TMO doping, in agreement with XRD data analysis.

The BET surface areas of our samples were determined and the values are listed in Table 2. ZnO exhibits a low surface area that reveal the effect of calcination as reported in the literature. It is determined that the TMO-doped ZnO samples show smaller surface area in comparison to the surface area of pure ZnO. That surface area change was attributed to the particles aggregation and, thus, to the partial blockage of adsorption sites.

The optical characterization of materials allows the prediction of possible behavior of photocatalysts under illumination. Absorbance spectra, Fig. 3a, have been used to determine the optical band gap energy (Eg). The values of Eg (Table 2) were determined using the Tauc's plot method, Fig. 3b.

In all of cases, the band gap of TMO-doped ZnO are smaller in comparison to pure ZnO, being the smallest for the CoO/ZnO sample (2.46 eV). These results are in agreement with other works such as NiO/ZnO nanorods and CoO/ZnO nanofibers. As a consequence of the coupling of MTO and ZnO in the heterojunction more electrons are freely transferred from MTO of the TMO (with higher Fermi level) to ZnO (with lower level), promoting the separation of holes and electrons and, then, effective heterojunctions are formed. Therefore, the band gap closing can facilitate stepping electrons from the valence band to the conduction band as that reported in the literature for CuO-ZnO nanocomposites. That band gap closing leads to the photocatalytic activity improvement of the TMO-doped ZnO nanocomposites.

Photocatalytic H2O2 decomposition. Control test. The reaction in the dark condition as a function of time was followed. This control test confirmed that H2O2 is not decomposed in the dark condition. In the absence of catalist but under visible light irradiation, 0.65 × 10^-4 mol of O2 were produced and this control test allows us affirm that decomposition rates are related only to the effect of light on the TMO/ZnO systems (Fig. 4).

Photocatalytic systems. To understand the behavior of the materials in the reaction, we follow the O2 formation as a function of time under visible light irradiation.

The Table 3 shows the production of O2 form the decomposition of H2O2 during 20 min. As observed, there is a progressive increase in the O2 production. The conducting properties of the catalysts enhance the production of O2 and therefore the H2O2 decomposition.

The Fig. 5 shows the kinetic study of the photocatalytic decomposition of H2O2 carried out using the TMO-ZnO systems. As observed, the O2 production obeys the first-order law, as previously reported in the literature. The inset shows the initial rate (the slopes of the plots correspond to the rate constants). These rate constants are different and indicate distinct response of the systems, Table 4.

The irradiation without catalysts just promotes a weak H2O2 decomposition and leads to the O2 production 0.65 × 10^-4 mol, while the use of ZnO increases the O2 production up to 1.5 times (Table 3) demonstrating the catalytic power of ZnO. Nevertheless, the doping of ZnO with MTO significantly enhance the photocatalytic power of ZnO, which suggests that the surface charge transfer process should increase, meanwhile, the electron—hole recombination rate should decrease. In fact, the O2 production (Table 3) can go up to 3.95 × 10^-4 mol in the presence of CoO/ZnO, which seems to be the system with the highest activity. Additionally, it was determined that the Aerosil TiO2-P25 powder can be exceed by the ZnO doping with transition metal oxides, specially CuO, Cu2O, MnO2 and CoO.

Table 4 shows the reaction rate and the catalytic activity values. These parameters corroborate that the best dopant oxides are those previously mentioned. These results have been correlated with the redox potential and the amount of loaded metal ion. Mn⁴⁺, Cu²⁺, Co²⁺, Cu¹⁺ and Fe³⁺ have positive values and the low rate observed with Cr³⁺ and Ni²⁺ is in agreement with their negative redox potentials.

The introduction of TMO in ZnO improves its absorption in the visible region, Fig. 3a. This leads to reduce the extent of undesired recombination of charge carrier resulting in a better activity and a decrease of the...

value of band gap, which leads to higher efficiency of photocatalysts due to a better overlap with the light source spectrum. The \( \text{H}_2\text{O}_2 \) decomposition under visible light irradiation by different semiconductors SC as TiO\(_2\)\(^{31}\) or MnO\(_2\)\(^{35}\) has been studied and the mechanism is based on the oxidation–reduction properties of SC. For ZnO can be understood as follows: the irradiation of ZnO leads to excited state that can be expressed as ZnO (\( e^- \), \( h^+ \)) (reaction R.1). The electron in the conduction band -CB- is available for transference (reaction R.2) while photoinduced valence band holes is open for donation (reaction R.3).

\[
\text{ZnO} \xrightarrow{hv} \text{ZnO} (e^-, h^+) \quad \text{(R.1)}
\]

\[
h^+ + \text{H}_2\text{O}_2 \rightarrow \text{H}^+ + \text{HO}_2 \quad \text{(R.2)}
\]

\[
e^- + \text{H}_2\text{O}_2 \rightarrow \text{HO}^- + \text{OH}^- \quad \text{(R.3)}
\]

\[ \text{H}_2\text{O}_2 \rightarrow 1/2\text{O}_2 + \text{H}_2\text{O} \]  

(R.4)

A direct interfacial charge transfer mechanism is proposed for the visible light activity in M\textsuperscript{a+}-modified samples\textsuperscript{52}. Firstly, the adsorption of H\textsubscript{2}O\textsubscript{2} by the TMO/ZnO system releases H\textsuperscript{+} ions (reaction R.5). The electrons transferred to the CB of TMO from the valence band -VB- of ZnO lead to the metal reduction (reaction R.6). The catalyst regeneration step involves the HO\textsuperscript{-} reduction to HO\textsuperscript{-} \textsuperscript{54}. (reaction R.8).

\[ \text{M}^{a+}/\text{ZnO} + \text{H}_2\text{O}_2 \rightarrow \text{M}^{a+}/\text{ZnO} (\text{HO}_2)^- + \text{H}^+ \]  

(R.5)

\[ \text{M}^{a+}/\text{ZnO} (\text{HO}_2)^- + \text{H}^+ \xrightarrow{\text{hv}} \text{M}^{(a-1)+}/\text{ZnO} + \text{HO}_2 \]  

(R.6)

\[ \text{HO}_2 + \text{H}_2\text{O}_2 \rightarrow \text{HO}^- + \text{O}_2 + \text{H}_2\text{O} \]  

(R.7)

\[ \text{M}^{(a-1)+}/\text{ZnO} + \text{HO}^- \rightarrow \text{M}^{a+}/\text{ZnO} + \text{HO}^- \]  

(R.8)

Therefore, in the two pathways, the free radicals HO\textsubscript{2} (R.2 and R.6) or HO \textsuperscript{-} (R.3) induce the chain reactions sequence to produce the final products, \text{H}_2\text{O} and \text{O}_2 (reaction R.4 and R.7).

**Methods**

**Preparation of ZnO and MTO-doped ZnO.** ZnO and MTO-doped ZnO were prepared by the sol–gel method using a precursor alkaline solution composed of zinc acetate dihydrate dissolved in methanol, as described in a literature\textsuperscript{53}. In all cases, the dopant source of MT was nitrate except in the case of Mn, which was chloride. In a representative preparation, ZnO and MTO-doped ZnO were synthesized by the slow hydrolysis of zinc acetate using KOH as precursor. Zinc acetate dehydrate and a dopant were first dissolved in methanol and mixed together with a KOH solution (0.4 M) for obtain a clear and homogeneous solution. The solution was stirred at 60 °C for 2 h. Finally, the gel washed, dried and powdered before calcinations at 450 °C for eight hours in a muffle furnace. In Table 2 is shown the doped metal content determined from XRF measurements.

**Characterization of ZnO and MTO-doped ZnO.** X-ray diffraction analysis was performed using a RIGAKU Ultima IV diffractometer, with a Cu-K\textsubscript{α} as radiation source and Ni-filtered with CXB monochromator. Operating voltage was 45 kV with beam current of 15 mA. The measurements were performed at step widths of 0.05 and the scan rate was maintained at 2° min\textsuperscript{-1}. The XRD of the samples were performed in the 20 range of 20–70° as in\textsuperscript{54}. Additionally, the XRD data were analyzed using the Rietveld refinement method via the FullProf program. QUALX2.0 software was used for phase identification in the qualitative analysis from powder diffraction data.

Transmission electron microscopy (TEM) images were obtained by using a microscope (JOEL, model 1011) to determine the morphology, the mean particles size and the size distribution as in\textsuperscript{54}. The content of metal was estimated by Energy Dispersive X-ray technique using a EDX-720 Shimadzu Fluorescence Spectrometer (XRF). The solids were prepared as loose powder. The analysis was made using a Rh X-ray tube for 200 s under vacuum. The UV–Vis spectra of samples were recorded in the range of 220–1000 nm using UV-2600 Shimadzu spectrophotometer.

For nitrogen adsorption–desorption, the measures were made at –196 °C with a Fisons Sorptomatic 1990, after outgassing at 10\textsuperscript{-3} Pa for 24 h at ambient temperature.

**Photocatalytic degradation of H\textsubscript{2}O\textsubscript{2}.** Degradation of H\textsubscript{2}O\textsubscript{2} under visible light simulated conditions, with an halogen lamp (300 W, 220 V, \( \lambda \geq 400 \) nm), was used to evaluate the photocatalytic activity of ZnO and MTO-doped ZnO following the report made by Paéz et al.\textsuperscript{35}. The initial pH was kept between 4.6–5.1. 5 mg of solid was suspended in 50 mL of deionized water in the reactor and ultra-sounded for 30 min; when the temperature was 20 °C, 10 mL of H\textsubscript{2}O\textsubscript{2} solution were injected into the solid suspension and the lamp was turned on under visible light radiation. The production (in mol) of oxygen was calculated by the change in H\textsubscript{2}O\textsubscript{2} concentration during photocatalytic run and has been determined from Eq. (1).

\[ C = C_0 - 2 \times \frac{P V_g}{R T V_L} \]  

(1)

where C is the concentration of H\textsubscript{2}O\textsubscript{2} at time t (mol L\textsuperscript{-1}), C\textsubscript{0} the initial concentration of H\textsubscript{2}O\textsubscript{2} (6.5 mol L\textsuperscript{-1}), P the atmospheric pressure (\( \approx 101.3 \) kPa), R is the gas constant (8.314 L kPa mol\textsuperscript{-1} K\textsuperscript{-1}), V\textsubscript{L} the total volume of solution (0.015 L), T is the room temperature and V\textsubscript{g} corresponds to the integrated volume of gas liberated until time t (L) at atmospheric pressure measured by the devices.

**Conclusion**

TMO/ZnO nanocomposites were successfully synthesized and tested their photocatalytic activity for H\textsubscript{2}O\textsubscript{2}. The morphological and structural results confirmed that the TMO doping did not provoke the ions substitution in the ZnO lattices and that the ZnO structure is not affected. Optical measurements showed the ZnO band gap decrease with the doping. It is found that the doping reduces the electron–hole recombination rate, which improves the absorption in the visible region and leads to a significantly enhancement of sunlight photocatalytic activity.
performance of ZnO. The surface-mediated decomposition of H₂O₂ and the consequent production of O₂ were used to measure the photocatalytic power of the TMO/ZnO nanocomposites. The resultant reaction rate values are explained based on the combination of redox potential of metal of the TMO and a better absorption of visible light due to the presence of TMO in the TMO/ZnO system. Our findings indicate that Cu₂O/ZnO, CuO/ZnO, MoO₂/ZnO and CoO/ZnO systems overcomes the photocatalytic activity of most popular commercial photocatalyst: Aerioxide P25. Therefore, our results indicate that TMO/ZnO systems can substitute the current commercial photocatalysts.

Acknowledgements
The director of this research, Beto Páez, passed away this July 12th. Beto was a researcher, full of ideas, super enthusiastic, super nice ... and in love. This paper is dedicated to the memory of Dr. Carlos Alberto (Beto) Páez (July 1974–July 2020).

Author contributions
A.E.R. and C.A.P. conceived and designed the experiments and analyzed the data. M.M., J.E.R. and J.A.C. characterized the optical properties of the samples. A.E.R. in collaboration with J.L.L. characterized the structure of samples by TEM, XRD, XRF. The manuscript was written by A.E.R. and C.A.P. with input from J.A.C. and B.H.

Funding
A. Ramírez acknowledges the financial support obtained from CNPq/CLAF (Fellowship for Postdoctoral Young Research Program), Belgian F.R.S.-FNRS and Universidad del Cauca (VRI ID-4377). C.A. Páez and B. Heinrichs thank the Belgian Fondes de la Recherche Fondamentale Collective (F.R.F.C), the Ministère de la Région Wallonne. JAHC thanks the Brazilian agencies CNPq (301455/2017-1, 443652/2018-0) and FAPDF (00193.0000151/2019-20) for the financial support.

Competing interests
The authors declare no competing interests.
