Key words: tumor immune microenvironment, tumor immunotherapy, immune cells, non-immune cells, immune checkpoint

Abstract. Tumor immunotherapy is considered to be a novel and promising therapy for tumors and it has recently become a hot research topic. The clinical success of tumor immunotherapy has been notable, but it has been less than totally satisfactory because tumor immunotherapy has performed poorly in numerous patients although it has shown appreciable efficacy in some patients. A minority of patients demonstrate durable responses but the majority of patients do not respond to tumor immunotherapy as the tumor immune microenvironment (TIME) is different in different patients for different tumor types. The success of tumor immunotherapy may be affected by the heterogeneity of the tumor immune microenvironment and its components, as these vary widely during neoplastic progression. The deepening of research and the development of technology have improved our understanding of the complexity and heterogeneity of the tumor immune microenvironment and its components, and their effects on response to tumor immunotherapy. Therefore, investigating the tumor immune microenvironment and its components and elucidating their association with tumor immunotherapy should improve the ability to study, predict and guide immunotherapeutic responsiveness, and uncover new therapeutic targets.

1. Introduction

Over the past decade, tumor treatment has been revolutionized by moving away from chemotherapy and radiation and toward tumor immunotherapy and targeted therapy. Tumor immunotherapy, which modulates immune responses against tumors, has shown appreciable efficacy in multiple cancer types and is considered to be a novel and promising therapy for tumors. However, the efficacy of tumor immunotherapy has been found to be poor in the majority of patients, despite its notable efficacy in a appreciable proportion of patients with cancer (1-3). It has been reported that the hyporesponsiveness or unresponsiveness of patients to tumor immunotherapy may be due to the heterogeneity of the tumor immune microenvironment (TIME) (4,5). The TIME and its components may vary widely during neoplastic progression and among different patients, and these variations, as well as the heterogeneity of the TIME and its components, have a profound effect on the outcome of tumor immunotherapy (4,5). As a result, it is crucial to understand the roles of the TIME and its components during neoplastic progression and in different patients in order to improve the efficacy of tumor immunotherapy. With the deepening of research and the development of technology, our understanding of the complexity and heterogeneity of the TIME and its components and their effects on the response of patients to tumor immunotherapy has also improved. Deeper analysis of the complexity and heterogeneity of the TIME and its components is likely to uncover advanced biomarkers that may prove useful in identifying patient populations responsive to current tumor immunotherapy, and will benefit the search for novel targets for therapeutic modulation. The aim of the
present review was to provide a summary of the current knowledge centered around the TIME, focusing on its components and their association with tumor immunotherapy, in order to improve the ability to study, predict and guide immunotherapeutic responsiveness and uncover novel therapeutic targets.

2. Tumor cells and their function

Tumor cells, the dominant cellular components of the TIME, play an important role in the TIME, and they can directly inhibit the function of immune cells via secreting tumor antigens or creating a microenvironment that is not conducive to the metabolism of immune cells, thereby causing inactivation and inhibition of immune cell function (6). The tumor cells can also inhibit the function of immune cells through secreting inhibitory cytokines, capturing chemokines, secreting VEGF, which can suppress dendritic cell (DC) maturation and activate regulatory T cells (Tregs) directly, and activating immune checkpoints (6,7).

3. Immune cells and tumor immunotherapy

Immune cells, also a dominant cellular component of the TIME, serve an important role in the TIME, principally consist of T cells, B cells, monocytes-macrophages, natural killer (NK) cells, DCs and their subsets.

**T cells.** T cells, the main immune cells in the TIME, induce an antitumor immune response by recognizing antigens on tumor cells. The proportion and subsets of T cells in the TIME are the major factors affecting tumor progression (8).

Exhaustive T cells, a special subset of T cells, are characterized by dysmetabolic disorder, poor self-renewal ability, piecemeal loss of function, as well as sustained high expression of inhibitory immune checkpoints like cytotoxic lymphocyte antigen-4 (CTLA-4), programmed cell death protein-1 (PD-1), T-cell immunoglobulin and mucin-domain containing-3 (TIM-3), lymphocyte activation gene-3 (LAG-3) and T-cell immunoglobulin and ITIM domain (TIGIT), among others (8,9). T-cell exhaustion can be classified into ‘pre-exhaustion’ and ‘terminal exhaustion’ stages. ‘Pre-exhausted’ T cells retaining their T-cell function persist in vivo for 30-40 days and eventually differentiate into ‘terminally exhausted’ T cells (10,11). Studies show that ‘pre-exhausted’ T cells express PD-1, T-cell-specific transcription factor-1 as well as the chemokine receptor C-X-C chemokine receptor type 5 (12,13). PD-1 blockers primarily act on ‘pre-exhausted’ rather than ‘terminally exhausted’ T cells (10). Patients with melanoma with more ‘pre-exhausted’ T cells respond better to immune checkpoint blockade therapy for longer periods of time (10), indicating that increasing the numbers of ‘pre-exhausted’ T cells may contribute to better response to immune checkpoint blockers (10). Therefore, various approaches have been employed in an attempt to convert ‘terminally exhausted’ T cells into ‘pre-exhausted’ T cells or younger memory T cells (9,14).

Tregs, a CD4+ T-cell subset, specifically express CD25 and Foxp3 (15,16). Tregs bind to antigen-presenting cells (APCs) via expressing CTLA-4, reduce the secretion of co-stimulators CD80 and CD86, and suppress the co-stimulatory signals of T cells. It has been widely reported that Tregs inhibit the activation and function of T cells via these functions or directly act on T cells (17). By secreting immunosuppressive molecules, such as IL-10, IL-35, TGF-β, indole-2,3-dioxygenase and adenosine, Tregs lead to exhaustion of T cells (18). Activating Tregs can upregulate the expression of multiple suppressive immune checkpoints, such as PD-1, CTLA-4, TIM-3 and TIGIT (19), and also upregulate the expression of multiple molecules, which induce T-cell dysfunction, and transport molecules, such as CD39, CD73 and CCR4 (20). Reducing Treg numbers can reverse tumor-induced dysfunction of T cells (20). In brief, these findings indicate that changes of the subgroup and proportion of T cells in the TIME may affect the outcome of tumor immunotherapy.

**B cells.** Abundant B cells may be found in tumors and tumor-draining lymph nodes, and they are common immune cells of the TIME (21). B cells, serving as APCs or recruiting DCs, participate in antigen presentation and consequently adjust T-cell differentiation and activation (22). The extent of infiltration by B cells, particularly memory B cells and plasma cells, was shown to be associated with the progression and prognosis of gastric cancer (23). Antibody-induced circulating immune complexes can inhibit antitumor immune response, leading to poor prognosis in patients with pancreatic ductal adenocarcinoma and bone marrow tumors (24,25). Lymphotoxin secreted by B cells can accelerate tumor angiogenesis via activating STAT3 signaling, which in turn promotes cell proliferation in prostate cancer, melanoma and lung cancer (26). B cells can also promote bladder cancer metastasis by increasing the expression of extracellular matrix and remodeling-related genes (27). B cells, by secreting TGF-β, promote the production of reactive oxygen species and nitric oxide in myeloid cells, as well as the transformation of CD4+ T cells into Tregs, thereby suppressing the function of CD4+ T, CD8+ T and NK cells, and accelerating tumor growth and metastasis (26,28). CD20 monoclonal antibody was found to restrain the function of CD4+ and CD8+ T cells in melanoma (26).

In addition, B cells can directly destroy tumor cells and participate in antitumor immunity; they also express TNF-related apoptosis-inducing ligand to induce the lysis of melanoma cells and granulosin B to trigger the lysis of breast cancer cells, serving a protective role in patients with breast cancer and melanoma (26,29). Furthermore, activated B cells enhance T-cell-mediated antitumor responses in patients with cervical cancer (30). These findings suggest that B cells in the TIME have a dual function, as they may promote as well as inhibit tumor growth.

**NK cells.** NK cells, the predominant members of the innate lymphocyte family, are a class of natural immune cells that exhibit strong cytolytic activity against tumors (31). NK cells may be divided into the immature subset of CD56+ CD16- cells that can secrete a large quantity of cytokines, and the mature subset of CD56- CD16+ cells that are strongly cytotoxic (32,33). NK cells recognize and destroy target cells via surface receptors, such as TIGIT, LAG-3 and PD-1. Allogeneic NK cells can discern and kill acute myeloid leukemia (AML) cells in hematopoietic stem cell
transplantation (32), which is of significant therapeutic value in AML (34,35). NK cell activity is modulated by blocking NK cell immune checkpoint receptors, as NK cells express multiple immune checkpoint receptors, such as killer cell Ig-like receptor and CD94/NKG2A, and express multiple immune checkpoints, including TIM-3, TIGIT, CD96 and LAG-3, which can interact with their cognate ligands on tumor cells or on other immune cells. Moreover, NK cells are innate lymphoid cells that efficiently kill tumor cells without MHC specificity (36). A novel strategy often employed in tumor immunotherapy is through applying NK cell immune checkpoint inhibitors (37). The IgG4 anti-NKG2A antibody monalizumab was used to treat various solid tumors, and was shown to be generally well-tolerated (37,38). The combination of monalizumab and the PD-1/PD-L1 disrupting agent durvalumab was used to treat colorectal cancer, which was also well-tolerated. The disease in 11 patients was stable and the disease control rate was 24% at 16 weeks in the expansion cohort. In addition, the anti-EGFR antibody cetuximab is an established therapeutic approach to squamous cell carcinoma of the head and neck, acting through induction of antibody-dependent cytotoxicity through the CD16 (FcγRIII) receptor expressed on NK cells (39). The rationale for this approach relies on evidence that squamous cell carcinomas of the head and neck are strongly positive for HLA-E and are infiltrated by NK cells (40). This regimen was also well-tolerated, characterized mostly by grade 1-2 adverse events, with an overall response rate of 31% and disease stabilization rate of 54% (38). Furthermore, it is not necessary for NK cells to go through the process of antigen recognition, which indicates that NK cells can eliminate tumor cells without sensitization, preferentially eliminating tumor stem cells (41). It must be pointed out that the decrease in the number of NK cells may be associated with cancer risk (42). Compared with T cells, NK cells have a shorter persistence and may also represent a safer and more effective adoptive immunotherapy for solid tumors and hematological malignancies (43). Therefore, regulation of NK cell function and enhancement of NK cell toxicity are the dominant means of NK cell-based tumor immunotherapy (44,45).

DCs. DCs mobilize naive T cells differentiate into effector cells and, thus, exert antitumor immunomodulatory effects by recognizing foreign antigens. Lysosomal-associated membrane glycoprotein 3-positive DCs, a mature subset of DCs, can express a variety of immune-related ligands and regulate the functions of a variety of lymphocytes and their subsets (46). Reduced the recruitment and the number of CD103+ DC leads to poor infiltration and dysfunction of CD8+ T cells in the TIME (8). Compared with the untreated control, DC vaccines, alone or in combination with PD-1 inhibitors, have shown better tumor control and milder toxicity compared with the untreated control (47,48). The aforementioned findings indicate that DCs can affect the function of other immune cells in TIME.

Mononuclear macrophages. Tumor-associated macrophages (TAMs), the most abundant population of tumor-infiltrating immune cells, refers to the macrophages located in or near the tumor (49). In response to tumor antigen stimulation, macrophages can differentiate into two subtypes: The M1 subtype, which promotes antitumor immunity, and the M2 subtype, which plays a role in tumor progression (49). TAMs, which tend to differentiate into the M2 subtype, are involved in tumorigenesis and tumor progression (50). It has been reported that an increase in TAMs is associated with poor prognosis in patients with cancer (51). Nanocomposites can promote the transformation of M2 to M1 macrophages, suppress tumor angiogenesis, reshape the TIME, present antigens to T cells, stimulate T cells to release cytokines, stimulate NK cells to infiltrate to tumor cells, and activate antitumor immune response to kill tumor cells (52,53). Therefore, TAMs in the TIME also affect the outcome of tumor immunotherapy.

4. Non-immune cells and tumor immunotherapy

Fibroblasts. Fibroblasts, an important type of mesenchymal cells, maintain organ structure and homeostasis by secreting cytokines, chemokines, growth factors and extracellular matrix. Carcinoma-associated fibroblasts (CAFs) are among the most important immune cells in TIME, which attract and mobilize immunocytes with inhibitory function through the release of cytokines, such as IL-6 and TGF-β, as well as chemokines, such as C-X-C motif chemokine ligand (CXCL)1, CXCL12 and C-C motif chemokine ligand 2 (54). In addition, CAFs attract macrophages, T cells and NK cells to the tumor stroma (49) and they also induce resident macrophages and neutrophils to differentiate into M2 macrophages and N2 neutrophils, thereby serving an antitumor immunosuppressive role (55). It has been found that tumorigenic signals in melanoma interfere with T-cell-mediated anti-tumor responses by regulating the phenotype of CAFs (8). Paracrine signaling between tumor cells and fibroblasts can lead to chemoresistance, thereby negatively affecting chemotherapeutic efficacy in patients with breast cancer (56). CAFs induce phosphorylation of heat shock transcription factor-1 at S326, as well as proliferation, epithelial-to-mesenchymal transition and cancer stem cell-like transition of gallbladder cancer (GBC) cells by secreting thrombospondin-4 and binding to integrin α2, a transmembrane receptor on GBC cells (57). CAF exon LINC00659 accelerates the proliferation, invasion and migration of colorectal cancer cells via the microRNA-342-3p/annexin 2 axis (58). Activated CAFs promote the invasion and migration of ovarian cancer cells via the TGF-β/collagen type VI alpha 1 chain signaling pathway (59). These findings indicate that CAFs in the TIME can affect the functions of other immune cells and cytokines, the efficacy of tumor immunotherapy and tumor growth.

Vascular endothelial cells. Vascular endothelial cells, another non-immune cell type in the TIME, highly express PD-L1, which suppress CD8+ T-cell infiltration and facilitate Foxp3+ T-cell aggregation, thus forming a type of ‘immunosuppressive barrier’ (60). There are reports that anlotinib can downregulate the expression of PD-L1 in vascular endothelial cells to suppress tumor growth (60). These findings indicate that the vascular endothelial cells in the TIME also affect the functions of other immune cells and immune checkpoints to affect tumor immunotherapy.
5. Cytokines and tumor immunotherapy

IL-2, which activates and promotes the proliferation of T cells and NK cells, is the most promising cytokine in tumor immunotherapy (49). IL-2 activates aromatic hydrocarbon receptors to regulate CD8+ T-cell failure (61). Second-generation IL-2 based on CD122 can induce the production of NARA1 interleukin. NARA1 with longer half-life in vivo can completely avoid binding to CD25 and stimulate proliferation and activation of CD8+ T cells and NK cells more effectively (62).

IL-12 induces immunosuppressive deficiency during CD8+ T-cell differentiation (63). T cells pretreated with IL-12 can prevent CD8+ T cells from failing and enhance T-cell activation, thus boosting tumor clearance rate as well as reducing the risk of immune-related adverse events in patients with cancer (64). Recombinant IL-2, which has been approved by the US Food and Drug Administration for antitumor immunotherapy in metastatic kidney cancer and metastatic melanoma, has shown considerable therapeutic efficacy (49). It is reported that IL-12 does not only enhance the cytotoxicity of chimeric antigen receptor-T (CAR-T) cells, but can also reshape the TIME with more prominent CD4+ T-cell infiltration and fewer Tregs, which has a significant therapeutic effect on glioblastoma multiforme (65). It may be concluded that cytokines in the TIME can affect the function of immune cells and the efficacy of tumor immunotherapy.

6. Immune checkpoints and tumor immunotherapy

The application of immune checkpoint inhibitors has been a novel approach to and research hotspot in tumor immunotherapy in recent years, and has also shown considerable efficacy in the treatment of several tumors (66-68). First-generation immune checkpoint blockade tumor immunotherapy based on antibodies acts by blocking the interaction between receptors and/or ligand molecules, such as CTLA-4 and PD-1, that are involved in T-cell activation or reduced function (8).

PD-1 and PD-L1. PD-1, a member of the CD28 family, has two ligands with different expression patterns, PD-L1 (B7-H1) and PD-L2 (49), which can be used not only as an index of predicting tumor occurrence, but also as tumor prognostic index (69,70).
The combination of PD-1 with PD-L1, through the PI3K-AKT signaling pathway, releases immunosuppressive signals to inhibit the activation and proliferation of T cells, as well as to induce T-cell tolerance and exhaustion (49,71). It can also directly affect the proliferation of cytotoxic T cells through the SH2 containing protein tyrosine phosphatase-2/Ras/MAPK signaling pathway (72). PD-L1 alone or in combination with LAG-3 blocker and CXCL13 can contribute to delayed tumor growth and is associated with survival benefits (73,74). It has been pointed out that the monovalent bispecific antibody MEDI5752 can suppress PD-1 and CTLA-4, thus enhancing the blocking effect on activated PD-1+ T cells (75). Tumor immunotherapy with CTLA-4 and PD-1 monoclonal antibodies to block immune checkpoints has also achieved notable efficacy in a number of tumors (6,20). Pembrolizumab and durvalumab, as PD-1 monoclonal antibodies, have also shown marked efficacy in patients with esophageal cancer and are available as second-line treatment in patients with esophageal squamous cell carcinoma (ESCC) (76), which has been approved for clinical use for ESCC in Japan (46).

**LAG-3.** LAG-3 is an immune checkpoint expressed on the surface of various lymphocytes, including activated T cells, Tregs, B cells, NK cells and plasmacytoid DCs (49). LAG-3, which has a similar structure to CD4 but higher affinity to APCs, can compete with MHC II complex antigens, thereby inhibiting T-cell activation (49). Anti-LAG-3 monoclonal antibody, as well as bispecific antibodies targeting LAG-3 and PD-L1, can block the immunosuppression mediated by LAG-3 and PD-L1, thus enhancing the activity of T cells, in order to suppress cell proliferation and tumor growth, which may prove beneficial for numerous patients with cancer (77,78).

**TIGIT.** TIGIT is an immune checkpoint expressed on the surface of CD4+ T cells, CD8+ T cells, NK cells and Tregs, which has become a new hotspot in tumor immunotherapy in recent years. TIGIT combined with CD155 expressed by APCs or tumor cells in turn inhibits T cells and NK cells (79,80), which means that blocking TIGIT can facilitate the secretion of cytokines of CD4+ and CD8+ T cells, as well as restore the function of T cells and NK cells (81,82). It has been reported that TIGIT-blocking antibodies can accelerate the expression of cytokines and chemokines, thereby enhancing the antitumor immune response (83). TIGIT monitoring in the peripheral blood of patients with cancer may be used as an early detection marker for anti-PD-1 immunotherapy (84). Given all the aforementioned factors, TIGIT is a potential immune checkpoint in the TIME that can affect the function of immune cells and the efficacy of tumor immunotherapy.

**7. Conclusions**

In conclusion, the TIME is complex and has numerous components that may serve as tumor immunotherapy targets; furthermore, these components can interact and affect one another, which greatly affects the efficiency of tumor immunotherapy (Fig. 1). Moreover, the TIME differs among different patients and at different time points. Therefore, fully elucidating the changes occurring in the TIME and its components during tumor development in specific patients may be the key to administering effective tumor immunotherapy. Further research must be conducted in follow-up studies on tumor immunotherapy, in order to improve the specificity and effectiveness of this treatment modality in cancer management.
