The energy density of electrode materials for lithium-ion batteries has a major impact on the driving range of electric vehicles. In order to study the charge-discharge characteristics and application feasibility of Li-NiMnCo lithium-ion batteries for vehicles, a series of charge and discharge experiments were carried out with different rates of Li-NiMnCo lithium-ion batteries (the ratio of nickel, cobalt, and manganese was 5:2:3) in constant-current-constant-voltage mode. Firstly, a set of charge-discharge experiments were performed on different types of single-cell lithium-ion batteries. The results show that, under temperature conditions, the charge and discharge voltage-capacity curves of the four different types of Li-NiMnCo lithium batteries mentioned in the paper are not much different, and the charge-discharge characteristic curves are similar, indicating that different types of batteries with the same material composition have similar charge and discharge characteristics. Subsequently, a series of charge and discharge tests with different rates were conducted on such ternary lithium batteries. The characteristic curves with different charge-discharge rates indicate that this new type of ternary lithium battery has high current charge and discharge capability and is suitable for use in new energy electric vehicles. In addition, by analyzing the voltage-SOC curve under different magnification conditions, it is known that there is an approximate linear relationship between the battery voltage value and the SOC within a certain SOC range. The SOC value can be evaluated by the battery voltage, which should be controlled within a reasonable range to avoid overcharge or overdischarge of battery, thereby, causing permanent damage to the battery.

1. Introduction

Electric vehicles (EVs) are widely regarded as the most promising vehicles and have been developed rapidly in recent years. As a common energy storage link for new energy vehicles, power batteries are the bottleneck restricting the development of new energy vehicles. Their performance has an important impact on the driving range, charge, and safety of electric vehicles. The crucial performance of a power battery includes power density, energy density, cycle-life, cost, and safety [1, 2]. Lead-acid batteries have been widely used in many fields for the advantages of low price, rich resources, stable performance, safety and reliability, recyclable, reusable, etc. However, its specific energy and specific power are low, and its cycle-life is short. Nowadays, lead-acid batteries are rarely used as energy storage in EVs [3]. Compared with lead-acid batteries, nickel-metal hydride batteries have the advantages of pollution-free, large specific energy, large specific power, and long cycle life, but they have low single voltage, relatively high self-discharge rate, high price, and narrow operating temperature range. Nowadays, some EVs still use nickel-metal hydride batteries as energy storage components. Ultra capacitors have the advantages of long cycle-life, high specific power, fast charge speed, high operating temperature range, and high safety, but with little energy density. Ultra capacitors are widely used in EVs at present [4]. Lithium-ion batteries have excellent comprehensive performance of energy, power density, and cycle-life. Therefore, it is usually the best choice to use...
the lithium-ion battery as storage cell based on comprehensive consideration of its energy and power density and cycle-life for battery electric vehicles (BEVs), hybrid electric vehicles (HEVs), and plug-in hybrid electric vehicles (PHEVs). On the other hand, lithium-ion batteries require particular care in EV applications, such as overcurrent, overvoltage, or overcharge/discharge, which can cause significant safety issue to the batteries, noticeably accelerate the aging process, and even cause fire or explosion [5–7]. As one of new energy vehicle’s core technology, lithium-ion batteries may be widely used in the near future.

A lithium-ion single cell usually consists of a positive electrode, a negative electrode, and an electrolyte. The choice of electrode material determines the type and basic performance of the battery. At present, the new cathode materials discovered and synthesized include LiMn$_2$O$_4$, LiFePO$_4$, and Li-NiMnCo. Graphite can be used as a negative electrode material. By comparing the performance of several commonly used lithium-ion cathode materials, Li-NiMnCo materials have better comprehensive performance in terms of energy density, power density, and lifetime. In the past decade, the research on lithium-ion battery materials has attracted more and more researchers’ attention. Lithium-ion battery can be categorized into a Liquefied Lithium-Ion Battery (or LIB for short) and a Polymer Lithium-Ion Battery (or simply PLIB) according to the electrolyte. The polymer lithium-ion battery (PLB) can made into an ultrathin battery of wanton form and wanton size. Therefore, it has a broad application prospect. The charge-discharge characteristics and battery management of power lithium battery are the bottleneck of power technology development. The anode material is the core and key material of power lithium battery. The energy density of the anode material is closely related to the range of electric vehicles, and its cost accounts for about 1/3 of the cost of the lithium battery. Therefore, the development of anode materials with high energy density, long life, high safety, and low cost is crucial for the large-scale commercial use of lithium batteries and electric vehicles [8].

With the increasing research in the field of SOC (State of Charge) and SOH (State of Health) [9–17], nowadays improving the accuracy of the charge and discharge model of power batteries, especially lithium-ion batteries, is a crux research target. The available battery capacity can influence and even determine how long a battery can be fully charged and consequently, how far a vehicle can travel. The charge approaches can protect batteries form overheating, improve the capacity utilization, and prolong the service life, which is of great significance. There are four traditional charge approaches in EVs, including constant-current (CC) charge, constant-voltage (CV) charge, constant-current-constant-voltage (CC-CV) charge, and multistage constant-current (MCC) charge [18]. The CC charge is a rough but simple approach which is widely used for lithium-ion batteries [19]. In [20], the CC charge approach is first introduced to charge NiCd or NiMH batteries. Because the behaviours of batteries are highly dependent on the current rate in CC charge, therefore, it is a challenge to search a suitable charging current rate for CC charge. The charge speed is improved, but the battery aging process will be aggravated with large current rate in CC charge. While the high capacity utilization is achieved, too low current rate will slow down the battery charging speed with small current rate in CC charge. The proper battery charge approaches can be effectively designed according to enough accurate estimation of SOC, SOH, and temperature.

Lithium-ion power battery is a kind of high-performance energy storage cell. It is difficult to establish the mathematical model of the battery from the perspective of mechanism due to the complexity and strong nonlinearity of the battery. In order to provide data support and theoretical support for battery management, the test method is generally used to study the performance of the battery and a large number of experimental data are used to summarize the external characteristics of the battery in practical application. Promising applications such as EVs and smart grids have already encouraged many researchers to improve the performance of lithium-ion batteries. One area of research is to study anode battery materials. Previous studies have pointed out that there are a variety of materials can be used in anode materials for lithium-ion batteries. In this paper, we will focus on Li-NiCoMn lithium-ion batteries. We conducted a preliminary study on charge and discharge test data of Li-NiCoMn lithium-ion batteries, in order to analyze and study the charge and discharge characteristics of Li-NiCoMn batteries. A series of experiments were performed under different conditions. The contribution of this paper is threefold as follows.

(1) A series experiments were designed to determine capacity of Li-NiCoMn lithium-ion battery under different conditions in CC charge

(2) Charge and discharge characteristic curves of lithium-ion battery are obtained under different conditions in CC charge

(3) The experiments’ results can provide support for searching the proper charge current rate of battery in order to further improve charge performance

This paper is organized as follows. Section 2 details a set of experiments to determine the battery capacity of the Li-NiCoMn lithium-ion battery used in this paper. Section 3 describes a series of charge and discharge tests for a single Li-NiCoMn lithium-ion battery. Finally, Section 4 concludes this paper with a summary of contributions and with a discussion on possible extensions.

| Item                     | Specification            |
|--------------------------|--------------------------|
| Nominal voltage          | 3.7 V                    |
| Charge cutoff voltage    | 4.4 V                    |
| Discharge cutoff voltage | 2.75 V                   |
| Cell weight              | 195 g ± 15 g             |
| Thickness                | 5.0 ± 0.30 mm (full charge) |
| Cell dimension           | Width: 100.0 ± 2.0 mm (no folding) Height: 200.0 ± 2.0 mm |
2. Charge Characteristic Tests of Single Cell Li-NiCoMn Lithium-Ion Batteries

In this paper, the newly developed ternary Li-NiMnCo (the material ratio of nickel, manganese, and cobalt is 5:2:3) is selected as the test object. Its basic parameters are shown in Table 1. From Table 1, we can see that its nominal capacity is 10.0 AH, the charge cutoff voltage is 4.4 V, and the discharge cutoff voltage is 2.75 V. The other items such as cell weight and cell dimension are also shown in Table 1.

As shown in Figure 1, the schematic of the battery test bench consists of three parts: thermostat, BTS (battery testing system), and BTS Client. The operating range of the thermostat is \(-80^\circ \text{C} \sim 150^\circ \text{C}\) and the accuracy is 0.1\(^\circ \text{C}\), which can provide suitable and stable ambient temperature for the selected lithium-ion battery. The lithium-ion battery which is connected with the BTS through the battery clamp and is placed in the thermostat. The BTS Client is installed on the computer, which communicates with the BTS through TCP/IP. It can set the working condition of the BTS and complete the data collection and analysis functions of a series of experiments in this paper.

The objective of this paper is to study the behaviors of Li-NiCoMn cell. The test content includes the relationship between battery charge voltage and capacity, the relationship between battery charge voltage and SOC, battery charge efficiency, and charge characteristics of different rates in CC charge. The charge characteristics are summarized through a large number of tests, which can support for searching the proper charge-discharge current rate of battery in order to further improve charge-discharge performance.

2.1. Charge Capacity Tests of Single Cell Tenary Li-NiMnCo Lithium-Ion Batteries

In order to analyze the capacity of the selected ternary lithium battery material, a set of experiments were designed for different types of batteries in CC charging-discharge mode from different manufacturers. Table 2 shows the test results. In Table 2, the anode materials ZH and PU50D in the second column are from China Zhenhua (Group) Technology Co., Ltd. and Peking University Industrial Co., Ltd., and the third column cathode materials AML402 and Y1202 are from Dongguan Kaijin New Energy Technology Co., Ltd., and column 4 materials CG-CS and TCE8633 are two different electrolytes. The capacity in Table 1 is the corresponding charge battery capacity when each single cell is charged to a cutoff voltage of 4.4 V with constant rate 1 C.

From Table 2, it can be seen that the four different types of ternary Li-NiMnCo materials have higher charge capacity in the 1 C constant current charge mode. For different battery models, the difference in battery capacity charged is small.

2.2. Charge Characteristic Tests of Single Cell Tenary Li-NiMnCo Lithium-Ion Battery

In order to analyze the charge characteristics of the ternary Li-NiMnCo batteries shown in Table 2, a set of charge experiments for the four types of batteries in CC charge mode is designed in this section. The charge process is under normal temperature conditions and charge the cells with constant rate 1 C to 4.4 V. According to the experimental data, the relationship between voltage and capacity of four different models is obtained, as shown in Figure 2. Figure 3 shows the relationship between the charge voltage and SOC of four different types of ternary lithium batteries.

Comparing the four curves in Figure 2, it can be seen that the voltage capacity curves of different battery models are similar, which indicates that the anode materials are from different manufacturers, but having the same composition ratio of Ni, Mn, and Co has little difference in the charge characteristic curve of the single ternary lithium battery.

As shown in Figure 2, the operating voltage of the ternary lithium battery has gone through three stages: the voltage rises faster in the early and late stages of charge, while in the middle of charge, the charge curve tends to be flat. Based on this charge characteristic of the battery, we can use the piecewise function to estimate the charge capacity of the battery by measuring the voltage value of the battery. During the experiment, it should be noted that the battery voltage cannot be higher than the charge cutoff voltage, which will cause permanent damage to the battery.

### Table 2: Capacity of single Li-NiMnCo lithium-ion batteries.

| Battery model | Anode | Cathode | Electrolyte | Capacity (mAh) |
|---------------|-------|---------|-------------|---------------|
| #1            | ZH    | AML402  | CG-CS       | 11087         |
| #2            | ZH    | Y1202   | CG-CS       | 11001         |
| #3            | ZH    | Y1202   | TCE8633     | 11070         |
| #4            | PU50D | Y1202   | TCE8633     | 10709         |
As can be seen from Figure 3, in the range of SOC values of 15%-65%, the curve is approximately a straight line with a small slope. While in the range of SOC values from 65% to 100%, the curve approximation is also approximately a straight line with a slightly larger slope. For a hybrid car, the battery is often in a nonoperating state even during vehicle operation; the value of the OCV can be measured conveniently. Therefore, the value of the SOC can be predicted by the value of the OCV using the piecewise function according to this characteristic of the curve representation.
2.3. Rate Charge Characteristic Tests of Single Cell Tenary Li-NiMnCo Lithium-Ion Battery. The rate charge tests are carried out using single cell tenary Li-NiMnCo lithium-ion batteries in this section. Figures 4(a)–4(d) show the voltage capacity curves of four different types of lithium batteries; Figures 5(a)–5(d) show the SOC-OCV curves for four different types of lithium batteries.

As can be seen from Figures 4(a)–4(d), the ternary lithium batteries used have better charge characteristics, which can be charged at a higher rate. Comparing Figures 4(a)–4(d), it can be found that the battery charge curves are similar for 4 different types of batteries and each type of battery can accept 4 C constant rate charge. In addition, the charged battery capacity decreases with the charge rate increases.

Similarly, from Figures 5(a)–5(d), we can get that, under 4 C constant rate charge conditions, when the SOC value is greater than about 8%, the curves approximate straight lines. Correspondingly, the SOC value can also been estimated by measuring the voltage.

3. Discharge Characteristic Tests of Single Cell Li-NiCoMn Lithium-Ion Batteries

A series of discharge experiments are designed in this section, and the experimental objects are the same as in Section 2. The experimental process: discharge the cells with constant rate 0.5 C to cutoff voltage 2.75 V. Correspondingly, the test content includes the relationship between the discharge voltage and the capacity of the battery, the relationship between the
discharge voltage of the battery and the SOC, the discharge efficiency of the battery, and the discharge characteristics of different rates. The battery discharge performance is obtained through these tests, and the discharge characteristics of the battery are summarized, which lays a foundation for battery state estimation and health estimation, and provides a theoretical basis for rational and effective use of the battery.

3.1. Discharge Capacity Tests of Single Cell Ternary Li-NiMnCo Lithium-Ion Batteries. Table 3 shows the capacity of the four different types of ternary materials studied in this

| Model | Anode | Cathode | Electrolyte | Capacity |
|-------|-------|---------|-------------|----------|
| #1    | ZH    | AML402  | CG-CS       | 12142    |
| #2    | ZH    | YI202   | CG-CS       | 11785    |
| #3    | ZH    | YI202   | TCE8633     | 12002    |
| #4    | PU50D | YI202   | TCE8633     | 11614    |
paper. The capacity in the table is the corresponding discharge battery capacity when each single cell is discharged in the 1 C constant current discharge mode to a cutoff voltage of 2.75 V.

It can be seen from Table 3 that under the full power state, four different types of ternary Li-NiMnCo batteries can discharge a large amount of electricity when discharged to a cutoff voltage of 2.75 V in 1 C constant current discharge mode. The battery capacity difference of the four types of batteries is small.

3.2. Discharge Characteristic Tests of Single Cell Ternary Li-NiMnCo Lithium-Ion Battery. Similar to Section 2.2, in order to analyze the discharge characteristics of single Li-NiMnCo batteries, a set of discharge experiments were carried out for four types of batteries in this section. The discharge process is under normal temperature conditions, the batteries are discharged to a cutoff voltage of 2.75 V at a constant current with 1 C rate. According to the experimental data, the relationship between the voltage and the discharge capacity of four different models is obtained, as shown in Figure 6.

Figure 6: Discharge curves with the different types of batteries.

Figure 7 shows the OCV-SOC curves for four different types of lithium batteries discharged to cutoff voltage of 2.75 V.

By comparing the curves in Figure 6, the voltage drops rapidly in the initial stage of battery discharge, and then the discharge curve gradually becomes flat, and in the later stage of discharge, the voltage curve decreases linearly. Different types of batteries have certain differences in the later stage of discharge. Based on this discharge characteristic of the battery, we can use the piecewise function to estimate the discharge capacity of the battery by measuring the voltage value of the battery. From the characteristic curve of the later stage of discharge, it should be noted that the battery voltage cannot be lower than the discharge cutoff voltage; otherwise, overdischarge will occur, causing permanent damage to the battery. Figure 6 shows the discharge voltage as a function of SOC. As can be seen from Figure 7, in the range of the SOC of about 15% to 95%, the curve is approximately a straight line, and the slope is small, which has stable discharge performance. While the slope of the initial stage of discharge and the later stage of discharge is large. The SOC-OCV discharge curves of different types of batteries
are similar. We can use the piecewise function to predict the value of SOC by the value of OCV according to the characteristics of the curve representation.

3.3. Rate Discharge Characteristic Tests of Single Cell Tenary Li-NiMnCo Lithium-Ion Battery. In this section, the selected lithium battery are subjected to rate charge tests. Figures 8(a)–8(d) show the voltage capacity relationship of the four different types of batteries. Figures 9(a)–9(d) show the SOC-OCV relationship curves for the four different types of batteries.

It can be seen from Figures 9(a)–9(d) that the ternary Li-NiMnCo lithium-ion batteries studied have better discharge characteristics which can be discharged at a large rate. From the comparison of Figures 8(a)–8(d), it can be found that the discharge rate curves of the four different types of batteries are similar, and each type of battery can accept the 4 C discharge rate. In addition, it can be seen that the larger the discharge rate is, the smaller the discharged battery capacity is when discharged to a cutoff voltage of 2.75 V.

It can be seen from Figures 9(a)–9(d) that, under 4 C discharge rate conditions, correspondingly, we can also estimate the corresponding SOC value by measuring the voltage.

4. Conclusions

In this paper, the characteristics of different Li-NiMnCo lithium batteries are analyzed through a series of charge and discharge experiments. The results from experiments indicate that (1) at room temperature, the charge voltage of the Li-NiMnCo lithium batteries we studied in this paper increase rapidly in the early and late stages of the charge process, while the charge curves are smooth in the middle of the charge process. Based on these characteristics, the battery capacity can be accurately predicted by the terminal circuit voltage. Noticeably, the battery voltage must not exceed a preset threshold to avoid permanent damages to the battery. (2) Similarly, the discharge voltage curves of a Li-NiMnCo lithium battery has similar properties during discharge process at room temperature. The battery capacity also can be predict precisely by the terminal voltage according these characteristics. It concludes that the driving range of a lithium battery electric vehicle after a single charge should be controlled within a reasonable range charge to prevent permanent damage to the battery caused by excessive voltage decay in the later stage of discharge. (3) The Li-NiMnCo lithium battery studied in this paper has good rate charge
and discharge performance, as well as high current charge and discharge performance, which is suitable for electric vehicles. The results studied in this paper will provide a reference for searching proper charge-discharge current rate which can improve charge-discharge performance. In future work, we will focus on modeling and SOC estimation of Li-NiCoMn lithium-ion battery.
