Abstract

Aim: to evaluate the outcome of soft tissue reconstruction in case of open tibia fractures.

Materials and Methods: This is prospective study of minimum 30 patients admitted to East point College of Medical Sciences and Research Centre. Thorough local examination of injured limb was done and fracture graded according to Gustilos grading of fracture. Post debridement grading and radiological evaluation of fracture was recorded. Wound management was decided as per the condition of the patient and wound contamination-acute (<1 week), subacute (1-6 weeks), chronic (>6 weeks). Fracture management included external fixation, IM fixation, plate fixation (Internal fixation), limited internal fixation-pin/K-wire/Screws, and pin plaster. Type of coverage was planned-Split thickness skin grafting; fasciocutaneous flap, Muscle flap and SSG.

Results: Majority of the patients were found in age group between 21-30 years and least was in the age group of below 10 years. It was observed that majority of patients in our study were male (86.66%). RTA was the main mode of injury with 27 cases (90%). Out of 15 patients, 4 had head injury (13.33%), 5 had blunt abdomen trauma (16.66%), 4 patients had both head injury and blunt abdomen trauma (13.33%) and 2 patients had urinary bladder rupture (6.66%). Oblique fracture was found in 15 patients (50%), spiral in 10 cases (33.33%) and comminuted fracture in 5 cases (16.66%). Majority of patients underwent external fixation i.e. 17 cases (56.66%) followed by Internal fixation i.e.11 cases (36.66%). In this study excellent results were observed in 23 cases (76.66%), good in 5 cases (16.66%) and poor in 2 cases (6.66%).

Conclusion: Early soft tissue coverage in the acute phase (1-6 days) should be the priority in order to prevent bacterial colonisation especially hospital acquired; wound desiccation, sequestration of the exposed bone. External fixation should be contemplated in highly comminuted fractures with severe contamination and when wound closure is not possible.

Keywords: External fixation, tibia fracture, comminuted fracture, soft tissue reconstruction

Introduction

Although numerous studies demonstrate the efficacy of early soft tissue reconstruction in Type III open tibial injuries, the soft tissue coverage is typically separated from the tibial reconstruction in many units [1, 6], because most orthopaedic surgeons have limited experience in microsurgery. In many cases, Type III open tibial shaft fractures lead to massive bone loss that requires significant strategies to obtain bone union [8, 10]. Some surgeons recommend primary flap cover after debridement and stabilization of open fractures. Gopal S et al. [8] analyzed 80 open tibial diaphyseal fractures that were treated with early stabilization and flap cover. Their overall limb salvage rate was 95% and the rate of flap failure was 3.5%. They emphasized that internal fixation was preferable to external fixation and that their results were much better in those patients that had flap cover as part of the primary operative procedure. This may be a useful technique if it is logistically feasible and if the surgeon can guarantee that there is no residual contamination after debridement. In this study 30 cases of type IIIIB open tibia fractures have been studied where the results were obtained after fracture fixation with different techniques and soft tissue coverage.

Materials and Methods

This is prospective study of minimum 30 patients admitted to East point College of Medical Sciences and Research Centre, satisfying both the inclusion and exclusion criteria as stated below, after obtaining ethical committee approval.
Inclusion Criteria
- All patients below 60yrs of age
- All patients who have sustained tibial fractures falling into IIIB Gustilo’s Classification of open fractures.

Exclusion Criteria
- Open tibia fractures in patients above 60yrs of age
- Soft tissue loss secondary to pathological fractures of tibia: osteomyelitis and tumours
- Peripheral Vascular Disease
- Comorbidities - Diabetes mellitus
- Carcinomatous condition with cachexia
- Generalised atherosclerosis
- Serious medical illness

Method of collecting data
Once the patient was received in casualty after resuscitation measures the details of the cases regarding name, age, sex, occupation and address were recorded. Patients and the accompanying attendees were interviewed to determine mode of injury, time elapsed since injury. Thorough local examination of injured limb was done and fracture graded according to Gustilos grading of fracture. Patient was then posted for debridement of the wound. Post debridement grading and radiological evaluation of fracture was recorded. Wound management was decided as per the condition of the patient and wound contamination-acute (<1 week), subacute (1-6 weeks), chronic (>6 weeks). Fracture management included external fixation, IM fixation, plate fixation (Internal fixation), limited internal fixation-pin/K-wire/Screws, pin plaster. Type of coverage was planned-Split thickness skin grafting: fasciocutaneous flap, Muscle flap and SSG.

Post-op monitoring
Posts operatively patient were antibiotics were instituted as per wound culture and sensitivity. If external fixator was used then the patient was examined for pin tract infection, pin loosening, loss of fixation on 1st, 3rd, 5th day, 1 week, 2 weeks. If intramedullary fixation was used then patient was examined for infection, loosening and the loss of fixation 1st, 3rd, 5th day, 1 week, 2 weeks. In case of SSG wound was examined on 1st and 5th day, 1 week and at 2 weeks. In case of flap on day 1st, 3rd and 5th day, 1 week and at 2 weeks. Patients were started on knee and ankle exercises as per the stability of fixation and the soft tissue cover. Patients were discharged at around 14th to 20th post-operative day.

Follow up
The discharged patients were advised to report for follow up every month till adequate soft tissue coverage and the fracture union.
At every visit patient was examined clinically for wound coverage, knee and ankle movements and the radiograph was obtained to see for fracture union. Any complications noted were recorded.

Observations

Table 1: Age and Gender wise distribution of the study population

| Age (Years) | Number | %age |
|-------------|--------|------|
| 0-10        | Nil    | 0    |
| 11-20       | 3      | 10   |
| 21-30       | 10     | 33.33|
| 31-40       | 8      | 26.66|
| 41-50       | 4      | 13.33|
| 51-60       | 5      | 16.66|
| Gender      |        |      |
| Male        | 26     | 86.66|
| Female      | 4      | 13.33|

Table 2: Mode and associated injuries in the study population

| Mode of Injury   | Number | %age |
|------------------|--------|------|
| RTA              | 27     | 90   |
| Assault          | 3      | 10   |
| Fall             | 0      | 0    |
| Farmland         | 0      | 0    |
| Industrial       | 0      | 0    |
| Other            | 0      | 0    |
| Associated Injuries |      |      |
| Head injury      | 4      | 13.33%|
| Blunt abdomen trauma | 5   | 16.66%|
| Both             | 4      | 13.33%|
| Urological injury| 2      | 6.66%|

Table 3: Type of fracture and wound management

| Type of fracture | Number | %age |
|------------------|--------|------|
| Oblique          | 15     | 50%  |
| Spiral           | 10     | 33.33%|
| Comminuted       | 5      | 16.66%|
| Wound Management |        |      |
| Acute            | 9      | 30.0%|
| Sub-acute        | 9      | 30.0%|
| Chronic          | 12     | 40.0%|
Table 4: Type of fixation and coverage

| Type of Fixation | Number | %age |
|------------------|--------|------|
| Internal fixation| 11     | 36.66|
| External fixation| 17     | 56.66|
| None             | 2      | 6.66 |

| Type of coverage | Number | %age |
|------------------|--------|------|
| SSG              | 8      | 26.66|
| Fasciocutaneous flap | 13 | 43.33 |
| Muscle flap+SSG  | 9      | 30   |

Table 5: Outcome

| Scoring criteria | Grade | Result | No. of cases | Percentage |
|------------------|-------|--------|--------------|------------|
| Primary soft tissue cover+ Bone union + No major complications | A | Excellent | 23 | 76.66 |
| Primary soft tissue cover/cases requiring secondary procedure +Bone union + major complications (but finally both soft tissue and bone healing) | B | Good | 5 | 16.66 |
| Primary soft tissue cover/cases requiring secondary procedure +Bone non-union + major complications requiring amputation/repeated surgeries | C | Poor | 2 | 6.66 |

Discussion

Open tibia fractures especially type III B has plagued orthopaedic surgeons since times immorel. Their management protocol has evolved over years from amputation of the limb in the early era to the era of limb reconstruction involving neurovascular repair, soft tissue cover and efficient methods of skeletal fixation. Timing of soft tissue reconstruction has been controversial. Some surgeons favour staged procedure based upon the need for second look debridement. Others favour early coverage after skeletal stabilization to prevent nosocomial infection and secondary necrosis of expanded tissue. Godina (1986) \(^{(1)}\) and other pioneers changed the concept of primary repair and reconstruction of damaged tissue by advancing the phase of reconstruction from a delayed elective procedure to the day of injury \(^{(1)}\). Age of the patients is ranging from 18 years to 60 years with an average of 34.73 years and 48 patients are male (80%) and 12 patients female (20%).

In the present study mode of injury was road traffic accident in 44 patients (73.33%) and assault in 16 patients (26.66%). 15 patients had associated injuries. Out of 15 patients, 4 had head injury (6.67%), 5 had blunt abdomen trauma (8.33%), 4 patients had both head injury and blunt abdomen trauma (6.67%) and 2 patients had urinary bladder rupture (3.33%).

In our study 30 patients sustained oblique fractures (50%), 20 patients had spiral fractures (33.33%) and 10 patients had comminuted fractures (16.66%).

Soft tissue wound management was acute (less than 1 week) in 22 patients (36.66%), sub-acute (1-6 weeks) in 18 patients (30%) and chronic in 20 patients (33.33%).

In the present investigation for skeletal stabilization internal fixation was done in 29 patients (48.33%), external fixation in 29 patients (48.33%) and none in 2 patients (3.34%). This was found in agreement with the results reported by Schandelmaier et al. \(^{(12)}\), Court-Brown et al. \(^{(13)}\). Split thickness skin grafting was performed for 12 patients (20%), fasciocutaneous flap for 27 patients (45%) and muscle flap & split thickness skin graft for 21 patients (35%). This was found comparable with the findings observed by Keating et al. \(^{(14)}\) and Edwards et al. \(^{(15)}\), nearly 48% patients required fasciocutaneous flap, and muscle flap was done in 10-30% cases and SSG in 22-42% cases.
In our study cases managed with soft tissue cover on acute and sub-acute basis in group external fixation showed 3 patients with pin complications and 1 case with deep infection. In intramedullary nailing group 1 patient showed knee stiffness and deep infection in 1 case. In cases managed on chronic basis in the external fixation group 1 case showed non-union and 3 cases of pin complications and 2 cases of deep infection. In intramedullary nailing group 2 cases showed non-union and 2 cases of knee stiffness. In acute and sub-acutely managed wound complication rate was 22.22%. In chronically managed wound the complication rate of 41.6% was observed. In the study conducted by Gustilo RB et al. [9] and Byrd HS et al. [10] complication rates in chronically managed wounds was similar to our study. The differences were observed in the acute and sub-acutely managed wounds.

Conclusion
Initial debridement is important in reducing the infection rate and the other complications associated with soft tissue coverage and skeletal stabilisation. Initial wound swab at the time of admission is essential in order to recognise the flora/growth and institute appropriate antibiotics to reduce the infection rate. Early soft tissue coverage in the acute phase (1-6 days) should be the priority in order to prevent bacterial colonisation especially hospital acquired; wound desiccation, sequestration of the exposed bone. External fixation should be contemplated in highly comminuted fractures with severe contamination and when wound closure is not possible. Short term external fixation sequentially changed over to internal fixation combines the advantage of external as well as internal fixation as well as eliminates the disadvantages and limitation. In type III open fractures internal fixation can be contemplated when presentation is early with minimal contamination and soft tissue coverage can be obtained on acute basis. Timely meticulous wound management and early soft tissue coverage leads to early sound bone healing and early restoration of the function of the limb.
