Massive star winds are important contributors to the energy, momentum and chemical enrichment of the interstellar medium. Strong, organized and predominantly dipolar magnetic fields have been firmly detected in a small subset of massive O-type stars. Magnetic massive stars are known to exhibit phase-locked variability of numerous observable quantities that is hypothesized to arise due to the presence of an obliquely rotating magnetosphere formed via the magnetic confinement of their strong outflowing winds. Analyzing the observed modulations of magnetic O-type stars is thus a key step towards the better understanding of the physical processes that occur within their magnetospheres. The dynamical processes that lead to the formation of a magnetosphere are formally solved utilizing complex MHD simulations. Recently, an Analytic Dynamical Magnetosphere (ADM) model has been developed that can quickly be employed to compute the time-averaged density, temperature and velocity gradients within a dynamical magnetosphere. Here, we exploit the ADM model to compute photometric and polarimetric observables of magnetic Of?p stars, to test geometric models inferred from magnetometry. We showcase important results on the prototypical Of?p-type star HD 191612, that lead to a better characterization of massive star wind and magnetic properties.

1 Introduction

Magnetic O-type stars are a rare occurrence. Indeed, there are only 11 O-type stars in our Galaxy that are known to host firmly detected magnetic fields (Grunhut et al., 2017). These magnetic fields are predominantly dipolar and are generally oblique with respect to the rotation axis of the star. As a result, they are known to manifest phase-locked variability of numerous observable quantities, such as their photometric brightness, longitudinal magnetic field strength and line equivalent width.

In this paper we analyse the photometric and broadband linear polarimetric variability expected of an obliquely rotating magnetic O-type star. By matching models to observations, we can infer or constrain important wind and magnetic properties of a magnetic massive star that are important for the evolution and fate of such stars.

In section 2, we describe the numerical method that we have designed for photometric and polarimetric synthesis. Next, we attempt to model the observed light curve and Stokes Q and U curves of the prototypical O-type star, HD 191612. We conclude in the final section.
2 Numerical method

2.1 The ADM model

The presence of a strong and organized magnetic field can significantly alter the outflowing wind structure of a hot star. In fact, under strong magnetic confinement, the closed (presumably dipolar) magnetic field lines channel the winds into the formation of a co-rotating magnetosphere. For slowly rotating O-type stars, the trapped material falls back onto the star on a dynamical timescale, thus forming a so-called dynamical magnetosphere (e.g. Petit et al., 2013).

The dynamics of such a magnetosphere can be formally understood using sophisticated 2D or 3D magnetohydrodynamic simulations (ud-Doula & Owocki, 2002; Ud-Doula et al., 2008, 2009; ud-Doula et al., 2013). However, an analytical model has recently been developed by Owocki et al. (2016) that can quickly compute the steady-state temperature, velocity and density structure (in 2D) of a dynamical magnetosphere. This analytical dynamical magnetosphere (ADM) model essentially serves as a time-averaged picture of the MHD simulations all while being easily adaptable to different stellar and magnetic properties. The input parameters that the ADM model requires are: the mass-feeding rate ($\dot{M}_{B=0}$), polar magnetic field strength ($B_d$), wind terminal velocity ($v_\infty$), stellar effective temperature ($T_{\text{eff}}$), stellar mass ($M_*$), and stellar radius ($R_*$). In the following we exploit the ADM model as a means to simulate the variability resulting from magnetospheres of magnetic O-type stars. To model an oblique magnetic rotator, we rotate the 2D results from ADM into a 3D grid (assuming azimuthal symmetry) and tilt the magnetic axis with respect to the rotation axis. Fig. 1 illustrates snapshots of the magnetosphere density structure computed from ADM viewed at several rotational phases ($\phi = 0.0, 0.1, 0.2, 0.3, 0.4, 0.5$). The magnetic axis is tilted by 45° with respect to the rotation axis of the star and the density structure is computed with input parameters based on the typical prototypical magnetic massive star HD 191612: $T_{\text{eff}} = 35\, \text{kK}$, $R_\star = 14.5\, R_\odot$, $M_\star = 30\, M_\odot$, $v_\infty = 2700\, \text{km s}^{-1}$, $\dot{M}_{B=0} = 10^{-6}\, M_\odot\, \text{yr}^{-1}$ and $B_d = 2.5\, \text{kG}$. We can see that magnetic confinement results in the formation of an overdensity region near the magnetic equator.

2.2 The photometric and polarimetric model

The presence of an obliquely rotating magnetosphere is suspected to be responsible for the modulations of the observable quantities of magnetic massive stars. As the star rotates, its own magnetosphere periodically occults the source star’s light. For hot stars with winds primarily dominated by the electron scattering opacity, the bulk of their photometric and polarimetric variability can be estimated under the single-electron scattering approximation. In this case, the photometric variability is determined by the column density, while the polarimetric variability is characterised by the general shape of the magnetosphere. Both of these quantities can be estimated by utilizing the ADM model to provide the density structure of the magnetosphere.

When observations are considered, it is important to consider the inclination angle of the stellar rotation axis ($i$), in addition to the magnetic obliquity ($\beta$). Figs. 2 and 3 display predicted photometric and polarimetric rotational modulations under two configurations: $i = 15^\circ$, $\beta = 45^\circ$ and $i = 75^\circ$, $\beta = 45^\circ$. The stellar and magnetic
Fig. 1: 3D rendering of the density structure computed with the ADM model. Red regions are high in density while green regions low in density. The field lines of a dipolar magnetic field are overplotted. The magnetic field axis (inclined green arrow) is tilted by 45° with respect to the rotation axis of the star (vertical yellow arrow). One-half of a rotation is illustrated.
Fig. 2: Mosaic of modelled photometric and polarimetric observable quantities for $i = 15^\circ$ and $\beta = 45^\circ$.

Fig. 3: Same as Fig. 2 but for $i = 75^\circ$ and $\beta = 45^\circ$. 
parameters are set to mimic those of HD 191612: $T_{\text{eff}} = 35 \text{kK}$, $R_\ast = 14.5 \, R_\odot$, $M_\ast = 30 \, M_\odot$ and $v_\infty = 2700 \, \text{km s}^{-1}$ and $B_d = 2.5 \pm 0.4 \, \text{kG}$. We can see that the photometric light curves are either single dipped (if $i + \beta < 90^\circ$) or double dipped (if $i + \beta > 90^\circ$). In contrast, the broadband Stokes $Q$ and $U$ curves are generally sinusoidal. In $Q - U$ space, the linear polarimetric variability appears as a single looped locus (if one of Stokes $Q$ or $U$ curve is single waved) or double looped (if both Stokes $Q$ and $U$ curves are double waved).

3 Application

HD 191612 is a well-studied, slowly rotating Of?p-type star. With a rotational period of $\sim 537 \, \text{d}$ and a magnetic field strength of $\sim 2.5 \, \text{kG}$, periodic modulations can be observed in its photometric brightness, longitudinal magnetic field strength and $H\alpha$ equivalent width (Wade et al., 2011). In the following, we attempt to model both the photometric and polarimetric variability of this star.

3.1 Fit to the photometry of HD 191612

The photometry for HD 191612 was retrieved from the Hipparcos archive, and were originally obtained between November 1989 and February 1993. The light curve was phased according to the period and ephemeris derived by Wade et al. (2011) utilizing a combination of all archival $H\alpha$ equivalent width measurements (see Fig. 4): $\text{JD} = 2,453,415.1(5) \pm 537.2(3) \times E$.

To model the Hipparcos light curve for HD 191612, we fix its stellar parameters to those obtained by Howarth et al. (2007). In addition, to further constrain the mass-feeding rate, we set the polar field strength to its inferred value of $2.5 \, \text{kG}$ (from longitudinal magnetic field measurements (see Wade et al., 2011)). The curve of best fit is shown in Fig. 4 with best-fit parameters listed in Table 1. We obtain a mass-feeding rate of $\log \dot{M}_{B=0} = -5.72^{+0.13}_{-0.05}$ and two possible magnetic geometries: $i = 27^{+13}_{-14}^\circ$ and $\beta = 61^{+13}_{-11}^\circ$, or $\beta = 27^{+13}_{-14}^\circ$ and $i = 61^{+13}_{-11}^\circ$.

3.2 Fit to the polarimetry of HD 191612

Ground-based linear polarimetry of HD 191612 was obtained from the IAGPOL polarimeter mounted on the Boller & Chivens telescope at OPD/LNA, Brazil. The data were taken between June 2011 and August 2016.

The polarimetric fitting is accomplished similarly to the photometric modelling. We fix the stellar properties to the known values for this star and in addition fix its detected magnetic polar field strength. We model the Stokes $Q$ and $U$ curves simultaneously (see Fig. 5) and constraining the magnetic geometry to $i = 21^{+22}_{-12}^\circ$, $\beta = 68^{+10}_{-19}^\circ$ with a mass-feeding rate of $\log \dot{M}_{B=0} = -5.79^{+0.13}_{-0.07}$ (see Table 2).

4 Discussion

In the previous section, we were successful in reproducing both the photometric and polarimetric variability of HD 191612. Our derived magnetic geometry is consistent with the tentative results from Wade et al. (2011). Implied from the longitudinal magnetic field modulations, their magnetic geometry was constrained to the family.

of solutions satisfying $i + \beta = 95^\circ \pm 10^\circ$. Similarly, we obtained $i + \beta = 88^{+5}_5$ from the photometry and $i + \beta = 89^{+16}_{-15}$ from the linear polarisation.

The ambiguity present in the geometric angles determined via the magnetic variations also affects the inferences from the photometric variations. This is an expected result as the modelling of these two observable quantities are degenerate to interchanges in the $i$ and $\beta$ angles. As a result, they cannot be distinguished. However, the quantity that can be more reliably constrained is in fact the $i + \beta$ sum. In contrast, the magnetic geometry derived from the polarimetric variations does not suffer from the same degeneracy. In fact, the $i$ and $\beta$ angles can instead be constrained independently. For HD 191612, we obtained $i = 21^{+22}_{-12}$ and $\beta = 68^{+10}_{-19}$. While still satisfying the $i + \beta = 95^\circ + 10^\circ$ condition (derived from Wade et al., 2011), the geometry inferred from the polarimetry clearly favours one of the two possible geometries inferred from the photometry. This is a natural benefit of linear polarisation modelling.

Moreover, the mass-feeding rate obtained via photometric and polarimetric modelling are also in agreement. We stress that the mass-feeding rate encoded in the ADM model is in fact a hypothetical mass-loss rate in absence of a magnetic field. Wind quenching due to the presence of a magnetic field can effectively decrease the true measured mass-loss rate. According to ud-Doula & Owocki (2002), we can estimate the mass-loss rate via the scaling relation $\dot{M} = f_B \dot{M}_{B=0}$, where $f_B$ is the magnetic factor. For HD 191612, we obtain a magnetic factor of $\sim 0.19$ and therefore a reduced mass-loss rate of $\dot{M} = 10^{-6.44} \dot{M}_\odot \text{yr}^{-1}$ and $\dot{M} = 10^{-6.51} \dot{M}_\odot \text{yr}^{-1}$ inferred from the photometric and polarimetric modelling respectively. Via H$\alpha$ diagnostics, a clumped mass-loss rate of $10^{-5.8} \dot{M}_\odot \text{yr}^{-1}$ was derived by Howarth et al. (2007). For this value to be compatible with our results, a clumping factor in the order of $\sim 25$ is necessary. This is in agreement with typical clumping factors for these stars that are suspected to range between 2 and 100 (Puls et al., 2008).

5 Conclusion

We have described a numerical model capable of synthesising the photometric and polarimetric variability of magnetic hot stars due to magnetospheric scattering. We have applied our model to reproduce the rotational modulations observed in the photometry and polarimetry of HD 191612. Our modelling results constrain the magnetic geometry and mass-feeding rate to $i = 27^{+13}_{-14}$, $\beta = 61^{+13}_{-11}$ and $\log \dot{M}_{B=0} = -5.72^{+0.13}_{-0.05}$ from the photometry and to $i = 21^{+22}_{-12}$, $68^{+10}_{-19}$ and $\dot{M}_{B=0} = -5.79^{+0.13}_{-0.07}$ from the linear polarisation. A natural next step is to conduct a simultaneous fit of numerous observable quantities as a means to further constrain these parameters.
