ABSTRACT

Six laboratory experiments were carried out to investigate the effect of the fungicide Benomyl on pure cultures of some plant growth promoting bacteria (PGPB) and some fungi. The highest LD50 was recorded for Bacillus circulans and proved to be the most resistant to the fungicide, followed by Azospirillum braziliense, while Penicillium sp. was the most affected microorganism. LD50 values for the affected microorganisms were in 21–240 orders of magnitude lower in comparison with the LD50 value for Azospirillum braziliense. The results indicate a strong selectivity for Benomyl against Rhizobium meliloti and Penicillium sp. when compared to other microorganisms tested. The highest safety coefficient was recorded for Bacillus circulans followed by Azospirillum braziliense, while Rhizobium meliloti, showed the lowest safety coefficient value compared to other bacteria. The lowest toxicity index was recorded for Bacillus circulans and Azospirillum braziliense. The slope of the curves for Bacillus sp. and Rhizobium meliloti was steeper than that of the other curves, suggesting that even a slight increase of the dose of the fungicide can cause a very strong negative effect. In conclusion, Benomyl could be applied without restriction when using inocula based on growth promoting bacteria such as symbiotic nitrogen fixers (Rhizobium meliloti), non-symbiotic nitrogen fixers (Azospirillum braziliense) or potassium solibilizers (Bacillus circulans), given that the fungicide is applied within the range of the recommended field dose.

KEY WORDS: Aspergillus niger; Penicillium sp.; Fusarium oxysporum; Benomyl; toxicity

Introduction

Due to continuous use of pesticides, appreciable quantities of them and their degradation products may accumulate in the ecosystem. Prevailing data showed that only 2–3% of the applied chemical pesticides reach their targets, while the rest remains in the soil (US-EPA, 2005). Their excessive use causes serious damage to the ecosystem, terrestrial as well as aquatic, and consequently to the flora and fauna of the surroundings (Paliwal et al., 2009). This raises great alarm about the heavy contamination burden the soil is receiving. A great risk is being posed on soil microbes and there is interference with element cycles and entry into food chains. Among the pesticides used in Sudan, fungicides rank third after insecticides and herbicides. Fungicides were found to have the largest inhibition effect on soil microorganisms (Kruglov, 1991). One of the recently introduced fungicides in Sudan is Benlate, which is the commercial name for the active ingredient Benomyl or Methyl 1-(butylcarbamoyl)benzimidazole-2-ylcarbamate. It belongs to the benzimidazole family, a member of the carbamate group. It is selectively toxic to microorganisms and invertebrates. It is a systemic broad spectrum, protective and eradicant fungicide used for the control of many plant fungal pathogens and cold storage rots. The controlled fungi are mainly those causing powdery mildews, Botrytis, Fusarium basal rot, black spot and blossom rot. In Sudan it is used for the treatment of powdery mildews mainly in cucurbits and other vegetables. Seed protection and seed inoculation are frequently incompatible. One way of allowing for the successful infection of legume roots with Rhizobium after treatment of seeds with fungicides is to use a fungicide-resistant...
inoculant (Odeyemi & Alexander, 1977). The objective of this study is to investigate the toxicity of the fungicide Benomyl on some plant growth promoting bacteria and some fungi in pure cultures.

**Materials and methods**

The effect of Benomyl on pure cultures of nitrogen fixing bacteria (Rhizobium meliloti, Azospirillum braziliense), potassium solubilizing bacteria (Bacillus circulans), and some fungi (Aspergillus niger, Penicillium sp. and Fusarium oxysporum) was evaluated by determining $LD_{50}$. Benomyl effective concentration limits, Benomyl selectivity index (SI), Benomyl safety coefficient (SC) and toxicity index (TI). Benomyl (50% wettable powder) (M.wt: 290.3).

All microorganisms were used obtained from the Environment and Natural Resources Research Institute (ENRRI), National Centre for Research (NCR) – Khartoum – Sudan.

Two different media, Meat Peptone Agar and Czapeks Dox Agar were prepared by dissolving the ingredients of each (g) in one liter of distilled water as follows: **Meat Peptone Agar (MPA):** Meat extract 5.0; Peptone 7.5; Sodium chloride 5.0 and Agar 20.0. **Czapeks Dox Agar (CZA):** Sucrose 20.0; Sodium 2.0; Dipotassium hydrogen phosphate 1.0; Magnesium sulphate, hydrated (MgSO4.7H2O) 0.5; Potassium chloride 0.5; Calcium carbonate 3.0 and Agar 20.0 (Tepper *et al.*, 1993).

Benomyl effective concentration limits (20–80%) for Azospirillum braziliense, Rhizobium meliloti and Bacillus circulans were determined as suggested by Zinchenko *et al.* (1974). Each bacterial strain was grown on meat peptone broth for 24 hours, the culture was serially diluted and 0.5 ml of the proper dilution chosen for each microbe, was transferred to inoculate plates of MPA supplemented with different Benomyl concentrations. The plates were incubated at 28°C for 48 hours and then the observed colonies were counted. Benomyl concentrations used (g/L), suggested for each microbe according to its effective concentration limits, were: 3.83, 4.83, 5.33 and 6.33 for Rhizobium meliloti, 0.033, 0.233, 1.332 and 2.331 for Azospirillum braziliense, and 2.3, 2.8, 3.3, 3.8 and 4.8 for Bacillus circulans. A control set of MPA plates which were not supplemented with Benomyl was prepared for comparison. The concentrations of the fungicide that caused 50% destruction ($LD_{50}$) of the cells of pure cultures of the microorganisms were calculated by log-dose/probit regression line method Finney (1971) using computer software (Biostat, 2008).

For determining Benomyl effective concentration limits for fungi, Fusarium oxysporum, Aspergillus niger and Penicillium sp. were grown onto Czapeks Dox Agar plates for ten days and 1.1cm discs were then cut and seeded onto the surface of CZA plates (Shattock, 1988), which were previously supplemented with different Benomyl concentrations. Benomyl concentrations used were: 0.003, 0.0033, 0.0066, 0.01, 0.013 and 0.017 for both of Aspergillus niger and Penicillium sp., and 0.003, 0.01, 0.02, 0. 03 and 0.04 for Fusarium oxysporum. Control sets were included for comparison. Ten days later, the growth diameters in the treated and control plates were measured and recorded in cm.

Calculated $LD_{50}$ for each bacterial and fungal strain was used to calculate Benomyl selectivity Index (SI) and safety coefficient (SC) following Kruglov (1991):

$$SI = (LD_{50} \text{ of the first Microorganism})/(LD_{50} \text{ of the second Microorganism})$$

$$SC = (LD_{50})/(\text{Field dose})$$

Toxicity index (TI) of Benomyl was determined according to Sun (1950).

**Results**

The results of studying the influence of the fungicide Benomyl on growth and development of pure cultures of PGBP and some fungi are presented in Tables 1 and 2, Figures 1–6. The highest $LD_{50}$ (2 528.74 ppm) was recorded for *B. circulans* and the lowest (6.01 ppm) for *Penicillium* sp. (Tables 1 and 2). $LD_{50}$ values for the affected microorganisms were in 21–240 orders of magnitude lower in comparison with $LD_{50}$ value for *Azospirillum braziliense*. *Rhizobium meliloti*, *Azospirillum braziliense*, *Bacillus circulans*, *Aspergillus niger*, *Penicillium* sp. and *Fusarium oxysporum* showed different resistance to Benomyl with selectivity indexes (SI) in the range of 1.71–420.76. (Table 1). These results indicate that Benomyl has a selectivity index (SI) and safety coefficient (SC) following Kruglov (1991):

![Table 1. Effect of Benomyl on pure cultures of different microorganisms.](image)

| Species | $LD_{50}$ (ppm) | 1 | 2 | 3 | 4 | 5 | 6 |
|---------|----------------|---|---|---|---|---|---|
| *B. circulans* | 2528.74 | 1.75 | 37.27 | 280.04 | 359.20 | 420.76 |
| *Azospirillum* | 1444.87 | 21.30 | 160.01 | 205.24 | 240.41 |
| *Fusarium* | 67.85 | 7.51 | 9.64 | 11.29 |
| *Aspergillus* | 9.03 | 1.28 | 1.50 |
| *Rhizobium* | 7.04 | 1.17 |
| *Penicillium* | 6.01 |

![Table 2. Inhibition effect of Benomyl on growth of different microorganisms.](image)

| No | Microorganisms | $LD_{50}$ (ppm) | Safety Coefficient | Toxicity Index (%) |
|----|----------------|----------------|-------------------|-------------------|
| 1  | *B. circulans* | 2528.74 | 842913 | 0.24 |
| 2  | *Azospirillum* | 1444.87 | 481623 | 0.42 |
| 3  | *Fusarium* | 67.85 | 22616 | 8.86 |
| 4  | *Aspergillus* | 9.03 | 3010 | 66.56 |
| 5  | *Rhizobium* | 7.04 | 2346 | 85.37 |
| 6  | *Penicillium* | 6.01 | 2003 | 100 |

strong selectivity against \textit{R. meliloti} and \textit{Penicillium} sp. when compared to the other microorganisms tested. The safety coefficient of the most sensitive microorganism to Benomyl is more than 2000 compared to the other microorganisms tested. The highest safety coefficient (842.913) was recorded for the potassium solubilizing bacterium \textit{B. circulans}, followed by the free nitrogen fixing bacteria \textit{A. braziliense}, while the symbiotic nitrogen fixer \textit{R. meliloti} showed a low safety coefficient value of 2.346 compared to other microorganisms, except \textit{Penicillium} sp. The lowest toxicity index was recorded for \textit{B. circulans} and \textit{Azospirillum braziliense} while the highest was recorded for \textit{Penicillium} sp. and \textit{Rhizobium meliloti}. The slope of the curves for \textit{Bacillus} sp. and \textit{Rhizobium meliloti} is steeper than that of the other curves, suggesting that even a slight increase in the fungicide dose can cause a very strong negative effect on the growth of these microorganisms (Figures 1–6).
Discussion

The most sensitive microorganisms towards Benomyl, as determined by LD₅₀, were Rhizobium meliloti and Penicillium sp, as compared to the other microorganisms tested. The most tolerant was Bacillus circulans, followed by the free nitrogen fixing bacterium Azospirillum brasilienise. Osman et al. (2012) found the most sensitive microorganisms towards thiram, as determined by LD₅₀, to be Azospirillum and Pseudomonas aerantiaca, while the most tolerant were Falvobacterium followed by Fusarium oxysporum, Azonomas and Rhizobium meliloti. LD₅₀ values for the affected microorganisms were in 21–240 orders of magnitude lower in comparison with the LD₅₀ value for Azospirillum brasilienise. Kalinin et al. (2002) found that EC₅₀ values for resistant microorganisms towards azoxystrabin were in 3–5 orders of magnitude higher in comparison with EC₅₀ values for sensitive strains.

Srinivasulu et al. (2012) reported that Monocrotrophos and Chlorpyrifos pesticides caused a stimulatory effect on Azospirillum sp at doses of 2.5 to 5 kg/ha in laterite and vertisol soils. Diuron and Chlorotoluron were found to cause no effect on nitrogen fixers while Linuron caused a strong effect. Glyphosate and Methidathion were found to stimulate soil microbial growth, whereas Fenamiphos was detrimental to nitrification bacteria (Lo, 2010).

When Carbofuran, Chloromephos, Terbufos and Benfuracarb were tested for compatibility with Azospirillum lipoperorum on solid cultures, only Terbufos was found to induce a slight effect on growth (Revellin, 2010). Gomez et al. (1998) found that the pesticide Promopropylate did not affect the cell growth of Azospirillum brasilienise, while it was significantly reduced by Methidathion in chemically defined media at 10, 50, 100, 200 and 300 μg/ml.

Brominal, Cuprisal and Fenvalerate pesticides were found to suppress growth of Azospirillum chroococcum, Azospirillum brasilienise and Azospirillum lipoperorum at 10 and 50 ppm (Omar & Abd-Alla, 1992).

Results of this study showed different resistance of the microorganisms tested to Benomyl, with selectivity indexes (SI) in the range of 1.71–420.76. Osman et al. (2012) found selectivity indexes ranging from 1.496 to 7 447.5 for the fungicide Thiram against different microorganisms. The safety coefficient of the most sensitive microorganism to Benomyl is more than 2 000. According to Kalinin et al. (2002), a fungicide is considered safe for a given microorganism when its safety coefficient is more than 15. The safety coefficients for the microorganisms tested were within the range of 2003 to 842913. This indicates that the fungi tested might have developed resistance against Benomyl. Similar observations and conclusions were also drawn by (Cooksey, 1990 and Ogawa et al., 1983) for a number of fungi, including Aspergillus nidulans, Erysiphe spp. Penicillium spp. and Fusarium spp., against Benomyl. Favel et al. (2005) found that the fungicide Thiram at concentrations of 10, 30, 50 or 100 ppm a.i. did not kill Fusarium oxysporum strain CS-20 in the in vitro experiment, but it was most toxic to the fungus and significantly reduced its growth rate and final colony size at 30 ppm or greater. The lowest toxicity index was recorded for B. circulans and Azospirillum brasilienise, while the highest toxicity indices were recorded for Penicillium sp and Rhizobium meliloti. Daoud et al. (1990) found that the fungicide Benomyl was the most toxic of the pesticides tested against Alternaria spp. followed by fluazipof and Decis (deltamethrin). Osman et al. (2012) found that thiram was most toxic to Pseudomonas aerantiaca followed by Azospirillum. The lowest toxicity index was recorded for Fusarium oxysporum and Flavobacterium. The slope of the curves for Bacillus sp. and Rhizobium meliloti is steeper compared to the other curves, suggesting that even a slight increase of the dose of the fungicide can cause a very strong negative effect.

Kalinin et al. (2002) found that the slope of the dose–reaction curve for Klebsiella planticola was steeper than that of the curves for Pseudomonas putida, Azotobacter chroococcum and Clostridium acetobutilicum.

The results presented here indicate that Benomyl can be used in association with the microbial inoculants of biological nitrogen fixers and potassium solubilizers.
