Abstract
High-throughput phenotyping (HTP) has the potential to revolutionize plant breeding by providing scientists with exponentially more data than what is available through traditional observations. Even though data collection is rapidly increasing, the optimization of this data and its implementation in the breeding program has not been thoroughly explored. In an effort to apply HTP to the earliest stages of a plant breeding program, we extended field-based HTP pipelines to evaluate and extract data from spaced single plants. Using a panel of 340 winter wheat (\textit{Triticum aestivum} L.) lines planted in full plots and grid-spaced single plants for two growing seasons, we evaluated relationships between single plants and full plot yields. Normalized difference vegetation index (NDVI) was collected multiple times through the growing season using an unoccupied aerial vehicle. NDVI measurements during grain filling stage from both single plants and full plots were typically positively associated with their respective grain yield with correlation ranging from -0.22 to 0.74. The relationship between single plant NDVI and full plot yield, however, was variable between seasons ranging from -0.40 to 0.06. A genome-wide association analysis (GWAS) identified the same marker trait associations in both full plots and single plants, but also displayed variability between growing seasons. Strong genotype by environment interactions could impede selection on quantitative traits, yet these methods could provide an effective tool for plant breeding programs to quickly screen early-generation germplasm. Efficient use of early-generation, affordable HTP data could improve overall genetic gain in plant breeding.

INTRODUCTION

In the 20th century, the Green Revolution led to more than doubling production of many cereal grains (Pingali, 2012) while preventing large swaths of land from being degraded by agriculture (Stevenson et al., 2013). Today, agriculture faces a myriad of challenges including feeding an increasing population, more demand for agriculture products due to changing consumption patterns, climate change, and...
limited resources to increase agriculture productivity (The Royal Society, 2009). Meeting these needs requires an increased agriculture productivity of which superior plants play an integral role. Plant breeding is focused to improve agronomic performance of plants for food, fiber, feed, and fuel.

While the premise of plant breeding to improve populations has not changed, the tools of plant breeders has rapidly expanded in the 21st century. Meuwissen et al. (2001) proposed whole genome prediction (genomic selection [GS]) using dense genetic markers. This method functions by ensuring dense molecular markers are linked to quantitative trait loci and utilizing a training population that has been genotyped and phenotyped. Using the training population, a model can be developed that can predict individuals that have only been genotyped, potentially eliminating the need for large scale, costly field trials and phenotyping (Heffner et al., 2010; Poland, 2015). With the advent of next-generation sequencing (NGS) and the rapid decline in marker cost, GS has become a tractable plant breeding method for many staple crops including wheat (Triticum aestivum L.) (Belamkar et al., 2018; Poland et al., 2012b; Rutkoski et al., 2014), maize (Zea mays L.) (Zhang et al., 2017), sorghum (Sorghum bicolor (L.) Moench) (Muleta et al., 2019), potato (Solanum tuberosum L.) (Enciso-Rodriguez et al., 2018), as well as forage and tree species (Lin et al., 2014). Genomic selection has been used to increase yield (Crain et al., 2021a), improve disease resistance (Enciso-Rodriguez et al., 2018; Rutkoski et al., 2012), and speed the domestication of new crops (Crain et al., 2020). In many breeding applications, GS reduces the breeding cycle timeline improving genetic gains per unit time (Heffner et al., 2009).

A key component of GS is having an adequate training population that has been both genotyped and phenotyped. With the potential to use NGS for applications of marker and gene discovery for both model and nonmodel plants (Bräutigam & Gowik, 2010), phenotyping quickly became a limiting factor for genetic studies and plant breeding (Cobb et al., 2013; Poland, 2015; White et al., 2012). Genomic selection has led to a paradigm shift from phenotyping for plant evaluation and selection to phenotyping for GS model development with a greater emphasis on precision of measurement as well as phenotyping different sets of lines (Cobb et al., 2013; Heffner et al., 2009). For successful implementation of advanced breeding methodologies including GS, phenotyping has emerged as the critical bottleneck.

Realization of the phenomic bottleneck has led to the relatively new discipline of phenomics (Furbank & Tester, 2011). Over the past decade, a variety of tools have been developed to aid in high-throughput phenotyping (HTP) of plants. Phenomics now offers an array of tools from aerial platforms (Haghighattalab et al., 2016; Liebisch et al., 2015; Singh et al., 2019) to ground-based vehicles (Andrade-Sanchez et al., 2014; Barker et al., 2016; Deery et al., 2014) and even pushcarts (Crain et al., 2016; White & Conley, 2013). These phenotyping platforms can collect a variety of data from the electromagnetic spectrum including visible imagery, hyper-spectral data, and canopy temperature (reviewed in Fahlgren et al., 2015), which can be assigned to plots or plants providing data to evaluate genotypes (Haghighattalab et al., 2016; Wang et al., 2016).

The advances in HTP platforms have provided data sets that can be used to dissect plant growth and architecture (Busemeyer et al., 2013; Crain et al., 2017), identify quantitative trait loci (Tanger et al., 2017), and be used for GS and breeding decision making (Crain et al., 2018; Rutkoski et al., 2016). In addition to complementing genomic data, phenomics data is also being considered for directly making prediction and selection decisions in breeding. For example, Rincent et al. (2018) provided proof of concept of phenomic selection using near infrared spectroscopy to generate predictions as accurate as predictions using molecular markers (GS) in both wheat and poplar (Populus nigra L.). Work by Krause et al. (2019) also found that phenomics data could provide equivalent accuracy as molecular data for predictions in wheat. Phenomic predictions have also been developed in soybean (Parmley et al., 2019). In a separate study in soybean, Zhu et al. (2021) found that prediction accuracy of phenomic selection could be comparable to GS for plant height and seed yield. Regardless of whether phenotypic data is used in conjunction with molecular markers or independently, these techniques are providing novel methods for plant breeders to increase genetic gains.

Even though systems now exist to collect dense phenotypic and genotypic data, less work has been performed on how to best integrate these methods into a breeding program. While both Rutkoski et al. (2016) and Crain et al. (2018) concluded that adding phenotypic data could increase breeding

---

**Core Ideas**

- High-throughput phenotyping pipelines were translated to field-based single plant analysis.
- Traits from both single plant and full plots had common associated loci identified by GWAS.
- Variable correlations were found between single plants and full plots across traits and years.
- Genotype × environment interactions created challenges to accurately identify superior plants.
- High-throughput phenotyping data has potential use for early generation plant breeding.
efficiency in elite wheat breeding germplasm, both studies used material from the advance yield trials at the International Maize and Wheat Improvement Center. While representative of a typical breeding program, these trials were advanced lines that had already progressed through multiple stages of selection and were near the end of the breeding cycle. This material would have been inbred to at least the F$_5$ generation and there would have been additional time spent on seed increases through preliminary yield trials (Rajaram et al., 2002). In an effort to introduce phenotyping earlier into the breeding cycle, Krause et al. (2020) phenotyped breeding lines in unrepli-

cated small plots, which represents the first field plot evaluation as inbred lines derived from single plants. While this enabled high-throughput phenotyping earlier in the plant breeding cycle, multiple rounds of inbreeding and visual selection had already occurred, representing significant time and resource inputs while potentially decreasing the impact of advanced tools for selection in the breeding pipeline.

As any new technology can shift breeding activities throughout the cycle, maximum genetic gain will be achieved by optimally allocating resources within the plant breeding program given the balance of selection accuracy, selection intensity, and cost of evaluation. Resource allocation is a challenging problem that encompasses all stages of the breeding program and fluctuates as key selection targets, such as grain yield and disease resistance, vary throughout the stages of the breeding cycle (Heslot et al., 2015). For example, thousands of lines are often evaluated during the inbreeding stage of the cycle, yet only tens or hundreds may be evaluated in full, replicated plots later in the breeding cycle where the evaluations are more accurate yet more costly per line. The emergence of molecular tools (GS), HTP, and environmental data has brought new focus on how plant breeding programs can successfully implement and exploit these advances (Crossa et al., 2021).

A critical stage in the breeding pipeline is early generation testing of single plants, which could be a powerful entry point of improved selection methodologies within breeding programs. To date, early generation selection on single plants in wheat is typically visual and has not routinely included advanced tools (Rajaram et al., 2002). Thus, the potential of increasing selection gains in this stage of the breeding program has created strong research interest. Fischer and Rebetzke (2018) reviewed literature of early generation phenotyping in cereal grains and identified areas where selection would be possible in early stages of the breeding cycle. Many traits are indirectly related to grain yield, including some traits that may scale to the size of breeding programs including plant height, harvest index, kernel weight, and leaf angle (Quail et al., 1989). Additionally, other traits such as carbon isotope discrimination (Rebetzke et al., 2002) and stomatal aper-
ture traits (Condon et al., 2008) were correlated with yield; however, there is no current viable methods to scale these to the level of commercial breeding programs. Efficient and precise measurement of these traits could be used to enhance genetic gains at later stages of the breeding cycle.

High-throughput phenotyping methods could provide an opportunity to quantitatively evaluate early generation breeding material, where insufficient seed is available for large plots. With the right approach, such HTP screening could scale to the level of breeding programs to evaluate and select in populations of thousands to millions of individual plants (Deery & Jones, 2021). In addition, HTP measurements could provide a level of precision that is not available through visual or qualitative assessments (Duddu et al., 2019; Tanger et al., 2017). This could be useful for programs working with inbreeding as well as outcrossing species. Our objectives were to (a) adopt the methods of field-based HTP from plot level to single plant level, (b) evaluate the relationship between HTP measurements in single plants and full yield plots of the same genotype, and (c) provide proof of concept of early generation HTP within breeding programs.

2 MATERIALS AND METHODS

2.1 Plant material

We used 340 unique lines of which 274 have been used in the hard winter wheat association mapping panels described by Guttieri et al. (2015) and Grogan et al. (2016). These lines are representative of pedigrees and germplasm grown in the Great Plains regions and include lines developed in Colorado, Kansas, Montana, North Dakota, Nebraska, Oklahoma, South Dakota, and Texas from both public and private breeding programs. The majority of the lines are from release in the years of 1960–2010, with several historic lines (‘Bison’, ‘Cheyenne’, ‘Comanche’, ‘Kharkof’, ‘Kiowa’, ‘Tascosa’, and ‘Wichita’). The remaining 66 lines represented newer material and were additional advanced lines and cultivars from the region.

2.2 Experimental design

Field trials were conducted using all lines for two growing years in Kansas. The 2019–2020 season was at the Rocky Ford Experiment station (39°13’48.82” N, 96°34’41.87” W), while the 2019–2020 season was grown at the Ashland Bottoms Experiment Station (39°08’19.07” N, 96°38’21.00” W). To allow single plant comparisons to full yield plots, all entries were planted in two separate trials.
2.2.1 Association mapping panel

The association mapping (AM) panel was planted as a two-replicate, randomized complete block design where experimental plots were 2.4 m × 1.4 m (3.36 m²). Each plot consisted of six rows on 20 cm spacing and was seeded at a rate of 1.25 g m⁻². Plots were sown within the normal planting time for winter wheat in Kansas (24 Oct. 2018 and 17 Oct. 2019), and management practices for optimal yield were maintained. Herbicide (Finesse, 0.03 kg ha⁻¹ chlor-sulfuron + metsulfuron-methyl, and MCPA 0.84 kg ha⁻¹ 4-chloro-2-methylphenoxy) was applied on 9 Apr. 2019. Grain yield was harvested using a Kincaid 8XP plot combine (Kincaid Manufacturing). Grain weight was moisture corrected to 12% and recorded for each plot using a Harvest Master Classic GrainGage and Mirus harvest software (Juniper Systems).

2.2.2 Single plant association mapping panel

To replicate the situation of genetically distinct single plants during early stages of a breeding program, all AM entries were also planted in the single plant association mapping (SPAM) trials. The SPAM trial consisted of a four replicate, randomized complete block design, where single plants were grid spaced with 50 cm in 2018–2019. To provide better separation of individual plants, 2019–2020 trials were spaced on a 70-cm grid. Single seeds were started in greenhouse plugs on 12 Oct. 2018 and 8 Oct. 2019 respectively. Plants were allowed to grow to the two-leaf stage before being field transplanted on 5 Nov. 2018 and 25 Oct. 2019. Starting plants in plugs ensured that only one seed per entry was grown, after plants were transplanted to the field, management was the same for both AM and SPAM trials. At maturity, single plants were hand-harvested and threshed individually to obtain final plant grain weight.

2.3 Phenotypic data collection

Several hand-measured phenotypic parameters were collected in both the AM and SPAM panels. Heading date (Growth Stage 55, Zadoks et al., 1974) was recorded as the days after 1 January for each respective growing year. Spikelets spike⁻¹ and spike length, excluding the awns, were measured on three (subsamples) random spikes from the same plant in the SPAM panel and different plants in the AM panel. Number of fertile tillers, excluding any secondary or nonfertile tillers when the primary tillers reached physiological maturity, were counted for each plant in SPAM. In the AM panel, tillers m⁻² were determined by counting the number of tillers in a 50 cm length for the middle two rows of the AM plots. Tiller count was then transformed to spikes m⁻² using the following formula:

\[
\text{spikes m}^{-2} = \frac{\text{tiller count}}{2 \times 0.5 \text{ m} \times 0.20 \text{ m}}
\]  

where two rows of 0.5 m length were counted with a 0.20 m row spacing. In 2019, two separate tiller counts were completed per plot, but due to labor constraints in 2020 only one representative count of tillers were performed per plot. All field phenotypic data was digitally recorded in Field Book app (Rife & Poland, 2014). After harvest, thousand kernel weight was measured for all SPAM and AM plots.

2.4 High-throughput phenotyping data

High-throughput phenotyping data was collected during the spring growing season from AM and SPAM experiments each year using DJI Matrice 100 (DJI) unoccupied aerial vehicles (UAV) (quadcopter). The UAV was equipped with MicaSense RedEdge-M multispectral camera (MicaSense) that captured blue, red (660 nm), green, near infrared (840 nm), and red edge wavelengths. This information allowed us to calculate a number of plant parameters including plant height and vegetation indices including normalized difference vegetation index (NDVI) (Rouse et al., 1974):

\[
\text{NDVI} = \frac{\text{NIR} - \text{Red}}{\text{NIR} + \text{Red}}
\]

As NDVI has strong literature support of being a selection tool (Babar et al., 2006; Crain et al., 2017; Prasad et al., 2007), it is the main focus of analysis yet the methods developed should be applicable to other HTP measurements.

Following the methods of Haghigattalab et al. (2016) and Wang et al. (2020), white square tiles (30 cm × 30 cm) ground control points were distributed in the trials to improve geospatial accuracy and surveyed with an Emlid Reach RS (Emlid), Real-Time Kinematic Global Navigation Satellite System. Similar to Wang et al. (2020) flight speed and elevation were chosen to maintain a desired 80% overlap between parallel flight paths for orthomosaic image stitching. Flight missions were created using the CSIRO mission planner application (https://uavmissionplanner.netlify.app) and executed using the Litchi Mobile App (https://flylitchi.com/). The AM panel was flown at a height of 20 m above ground, while the SPAM panel was flown at 10 m above ground corresponding to a ground resolution of approximately 6 mm pixel⁻¹. Flight speed for all AM trials was 2.0 m s⁻¹ and SPAM trials were flown at 1.3 m s⁻¹ with all flights occurring within 1.5 h of solar noon (typically between 12:00 p.m. and 3:00 p.m.). A semi-automated image processing pipeline developed by
Wang et al. (2020) was used to orthomosaic all images and extract plot level data (NDVI). The processing pipeline used Agisoft ProtoScan Python API (Version 1.4.0, Agisoft) to create the orthomosaiced images, followed by trait extraction using Python scripts.

### 2.5 Statistical analysis

All statistical analyses were conducted in R version 4 (R Core Team, 2020). All subsample data, multiple measurements of spikelets spike$^{-1}$, spike length, and spike number on each plot, were averaged into a single phenotype before analysis. Models were fit separately for the AM and SPAM trials using a linear mixed model in the lme4 (Bates et al., 2015) R package. Best linear unbiased estimators (BLUEs) for each line were obtained from the emmeans (Lenth, 2020) R package with data combined across years using Equation 3:

$$y_{ijk} = \mu + g_i + t_j + r_{k(j)} + \beta_{ijk} + \varepsilon_{ijk} \quad (3)$$

Where $y_{ijk}$ is the phenotype, $\mu$ is the overall mean for the trait of interest, $g_i$ is the fixed effect for genotype $i$, $t_j$ is a random effect for year (2018–2019 or 2019–2020), independently and identically distributed $t_j \sim N(0, \sigma^2_t)$, $r_{k(j)}$ is the random effect for the $k$th replicate (AM $k = 1–2$, SPAM $k = 1–4$) nested within the $j$th growing season distributed as $r_{k(j)} \sim N(0, \sigma^2_r)$, $\beta_{ijk}$ is a fixed covariate for heading date for each genotype, year, replicate combination, and $\varepsilon_{ijk}$ is the residual effect for the $i$th genotype, $j$th year, and $k$th replicate distributed as $\varepsilon_{ijk} \sim N(0, \sigma^2_\varepsilon)$. To calculate heritability for traits across the two growing years, the fixed genotype effect was changed to a random effect. Broad sense heritability ($H^2$) or repeatability (Piepho & Möhring, 2007) was then calculated according to Holland et al. (2010) as:

$$H^2 = \frac{\sigma^2_g}{\sigma^2_g + \frac{\sigma^2_y}{y} + \frac{\sigma^2_r}{r}} \quad (4)$$

Where $\sigma^2_g$ is the genotypic variance, $\sigma^2_y$ is the variance attributed to genotype $\times$ year (genotype $\times$ environment [GxE]) variance, and $\sigma^2_\varepsilon$ is the residual error variance from Eq. 3, $y$ is the number of years (2), and $r$ is the number of replicates (AM = 2, SPAM = 4). Data was also analyzed within each year by dropping the year term from Eq. 3 resulting in Eq. 5:

$$y_{ik} = \mu + g_i + r_k + \beta_{ik} + \varepsilon_{ik} \quad (5)$$

where all terms are equivalent to Eq. 3. Broad sense heritability was calculated similarly by dropping the genotype by year term as Eq. 6:

$$H^2 = \frac{\sigma^2_g}{\sigma^2_g + \frac{\sigma^2_y}{y} + \frac{\sigma^2_r}{r}} \quad (6)$$

with all terms being defined as Eq. 4.

### 2.6 Genotypic data

A total of 321 unique lines from the AM panel detailed by Guttieri et al. (2015) and Grogan et al. (2016) were genotyped using genotyping-by-sequencing (GBS). Single nucleotide polymorphic (SNP) markers were discovered with GBS following the protocols of Poland et al. (2012a) with a two-enzyme digest using a rare-cutting (PstI) and common cutting (MspI) enzymes. The TASSELv2 pipeline (Glaubitz et al., 2008) and the Chinese Spring reference genome (International Wheat Genome Sequencing Consortium, 2014) were used to call SNPs. Samples were sequenced on multiple lanes of Illumina HiSeq to increase sample coverage, with three million average good-barcoded reads per sample (range: 876,286–12,001,293). A total of 112,248 unique SNPs were identified across all samples with an average of 20,741 SNPs identified per sample (range: 9,313–30,089). Data filtering consisted of removing individual markers with (a) a minor allele frequency < 0.05; (b) percent heterozygous > 0.05; and (c) percent missing < 0.5. Beagle version 4.1 was used to impute missing markers with default settings (Browning & Browning, 2016). The final genotypic data set for evaluating population structure and genome-wide association analysis (GWAS) consisted of 321 lines and 11,452 SNPs with an average of 520 SNPs per chromosome (range: 77–930). Overall, the D genome had the fewest SNPs (range: 77—304) with the B genome have the most SNPs (range: 260–930) per chromosome.

### 2.7 Genomic analysis

Using the SNP markers and phenotypic data, a GWAS was performed for both the AM and SPAM panels for each growing season to evaluate if common loci underpinned trait expression in both panels. This was completed as a proof of concept to see if traits measured on single plants had common marker trait associations in full plots. A mixed model following Yu et al. (2006) that can account for both population structure and genome-wide association analysis (GWAS) consisted of 321 lines and 11,452 SNPs with an average of 520 SNPs per chromosome (range: 77–930). A total of 112,248 unique SNPs were identified across all samples with an average of 20,741 SNPs identified per sample (range: 9,313–30,089). Data filtering consisted of removing individual markers with (a) a minor allele frequency < 0.05; (b) percent heterozygous > 0.05; and (c) percent missing < 0.5. Beagle version 4.1 was used to impute missing markers with default settings (Browning & Browning, 2016). The final genotypic data set for evaluating population structure and genome-wide association analysis (GWAS) consisted of 321 lines and 11,452 SNPs with an average of 520 SNPs per chromosome (range: 77–930). Overall, the D genome had the fewest SNPs (range: 77—304) with the B genome have the most SNPs (range: 260–930) per chromosome.
effects for population structure. $X$ is an $n \times p$ design matrix for population structure, $g$ is an $n \times 1$ vector of random genetic effects representing kinship, $Z$ is an $n \times n$ genomic relationship matrix, $\tau$ is the fixed marker effect for each marker tested individually, and $S$ is an $n \times 1$ vector of genotypes for the marker being tested, and $e$ is an $n \times 1$ vector of residuals. The `prcomp` R function was used to evaluate population structure using the genomic marker matrix of the 321 individuals and 11,452 marker. The genomic relationship matrix was calculated with the `A.mat` function in `rrBLUP` package (Endelman, 2011) according to the methods of Endelman and Jannink (2012). The first six principal components ($p = 6$), where each component explained more than 2% of the variation, were used to account for population structure. The P3D “population parameters previously determined” option was applied (Zhang et al., 2010). A false discovery rate of 0.1 was set to identify significant markers within the GWAS (Storey & Tibshirani, 2003), and the `qqman` (Turner, 2017) R package was used for data visualization.

3 | RESULTS

To translate field-based HTP methodology to single plants as well as determine the potential for HTP based selection early within the breeding program, we evaluated two growing years of full plot AM and SPAM panels under the same field conditions. Using fixed lines in the SPAM trials enabled us to create an artificial segregating population similar to individual $F_2$S that could be replicated from year to year. Additionally, having the full AM plots enabled a comparison between data measured on single plants and full plots for a proof of concept comparison between single plants and full plots. Data were collected from the AM and SPAM trials throughout the growing season with HTP data acquisition respectively spanning the growing season from stem elongation to ripening. Using UAVs equipped with sensors, there were 14 dates of data collection in AM and six in the SPAM trial in the 2018–2019 season of which 5 occurred on the same day for both trials. In 2019–2020, there were seven overlapping days for both AM and SPAM data collection and a total of 11 AM and nine SPAM data sets. The majority of the measurements occurred between mid-April to mid-June each year with 5–10 d between measurement. Each data collection resulted in approximately 700 and 500 images for AM and SPAM, respectively, that were processed (Figure 1) using a semi-automated pipeline to construct orthomosaic image and extract phenotypic traits. Broad-sense heritability, or repeatability, for the HTP data was higher for the AM plots than SPAM each season. In addition, $H^2$ was higher in the 2018–2019 season than in 2019–2020 with this trend observed for both AM and SPAM experiments (Figure 2, Supplementary Table 1).

3.1 | Association mapping panel

Within the AM trials, hand-measured phenotypes were evaluated to determine their relationship to grain yield. Across both growing years, plant height was the only trait that had a strong, consistent, negative correlation to grain yield (Figure 3 and 4). In the 2020 growing season, yield component traits of spikes m$^{-2}$, spikelets spike$^{-1}$, and thousand kernel weight were strongly associated with yield; however, in the 2019 season these traits were not significantly correlated to yield (Figure 3 and 4). Broad sense heritability for all traits was high at $H^2 = 0.45$ or greater, with the exception of spikes m$^{-2}$ having low heritability (Figure 3 and 4). Complementing the hand-measurements were the HTP data that was tested for correlation to full plot grain yield. Across both years after mid-April, correlations tended to be positive and significantly associated with grain yield with
the strongest correlations occurring after heading (Figure 5, Supplementary Table 2).

3.2 | Single plant association mapping panel

To evaluate the potential of phenotyping and selecting single plants, we collected both hand-measured traits and HTP data in the SPAM trial. In comparison to the full AM plots, plant height was positively associated with yield both seasons as was the number of spike plant\(^{-1}\) (Figure 3 and 4). Spikelets spike\(^{-1}\) had significant but opposing correlations between the two seasons, and thousand kernel weight was significant in 2020, yet not strongly associated with yield in 2019 (Figure 3 and 4). Broad-sense heritability was more variable between years compared to heritability observed in the full plots, yet most traits had \(H^2 > 0.4\) (Figure 3 and 4). Single plant NDVI was always positively associated with grain yield of the single plants and the correlations were of similar magnitude of correlations observed between full plot grain yield and NDVI (Figure 5).

3.3 | Relationship between single plants and full plots

Leveraging the fixed lines grown both in the AM and SPAM panels, allowed a comparison of how single plant could be...
Correlation between grain yield (GRYLD), heading date (HDDT), plant height (PTHT), spike length (SPKLNG), spikelets spike−1 (SPLSPK), spikes m−2 (SPNAREA), and thousand grain weight (TKW) for full plots (AM, panel a) and single plants (SPAM, panel b) for the 2019–2020 growing seasons in Manhattan, KS. The lower triangle in each panel has a scatter plot and line of best fit, the upper panel is the correlation between variable, and the diagonal is the broad-sense heritability of each trait.

Correlation between normalized difference vegetation index collected with high throughput phenotyping (HTP) and wheat grain yield (GY) for full plots (AM) and single plants (SPAM) for growing years (2018-2019, 2019–2020, panels a and b). The SPAM trial includes both correlation to single plants and the correlation to full plot yields. The area above or below the shaded region represents significant correlation values (p value < 0.001, n = 330).

3.4 | Genome-wide association analysis

A genome-wide association analysis was used to evaluate genetic architecture of trait expression in both the full plots and single plants. As the lines in each panel were fixed, this allowed us to test if trait expression was controlled under both growing conditions similarly and potentially allow selection on single plants for full plot characteristics. In the 2018–2019 growing season spikelets spike−1 showed a GWAS peak on chromosome 7A and spike length had high scoring markers on chromosome 2B for both AM and SPAM panels (Figure 6, Supplementary Figure 1). For these same traits, there were no associations found for either panel in 2019–2020 season. No significant associations were found for grain yield, thousand kernel weight, or spikes m−2 for either season of evaluation. Within the full plot AM panel, an association was found for plant height on chromosome 4B for both growing seasons. While no significant markers were identified within the
3.5 Genotype by environment interaction

Based on our contrasting findings of strong associations between traits in one season and then no association in another season, we evaluated data across years. This allowed us to partition variance components, including GxE, to determine the proportion of genetic and nongenetic effects. Across both years for the AM and SPAM panel, the heritability for grain yield was lower than for individual single seasons suggesting GxE interactions, and this trend carried through to several traits including thousand kernel weight. Across all traits, the proportion of genetic variance was less than 50% of total variation indicating strong environment and year effects complicating potential selection strategies (Figure 7).

4 DISCUSSION

4.1 Single plant HTP analysis

In an effort to extend HTP methodology to the earliest time points in the breeding program, we adapted existing process-
NDVI, these methods should be practical for a broad range of phenotypic measurements. For example, UAVs have been used to quantify plant height (Singh et al., 2019; Volpato et al., 2021), plant diseases (Wu et al., 2019), morphological and physiological traits such as heading date and presence of awns (Wang et al., 2019), and canopy temperature (Tattaris et al., 2016).

Previous research in early-generation plant phenotyping has been promising but limited by volume of phenotyping throughput (reviewed extensively by Fischer & Rebetzke, 2018), the advent of HTP methodology has opened the possibilities for expanded observation and selection in early generations. Even though our methods were applied to space planted individuals, we expect that continued refinement in algorithms and methodology will allow for evaluation of single plants that are more densely planted and not completely separated. Along with potential breeding application, we also expect that single plant evaluation could have important genetic applications. For example, Gyawali et al. (2019) conducted a GWAS using bulk segregant analysis of single plants to detect marker trait associations for plant height in maize.

4.2 Application to breeding programs

Many wheat breeding programs have minimal observations of early-generation material such that HTP could provide affordable and accessible data that can help enhance selection decisions. Using pipelined analysis, we envision that breeding programs could collect data on all generations of data while simultaneously making selection decisions. Instead of breeding lines being promoted to yield trials in advanced generations (F2 or later) with only breeder visual selection during each generation, lines could have multiple cycles of selection through impartial computational methods. As methods are refined, breeders could choose phenotypes that are expressed in single plants and maintained in full plots or optimal HTP phenotypes that are well correlated to full plot yield, even if the trait per se is not correlated or important for yield in full plots.

While we observed variable results between single plot yield and full plot yield for correlation of HTP data and grain yield, we did observe several GWAS hits that were similar between the two panels. For example, in 2018–2019 season spikelets spike−1 both had the same significant markers. In addition, a significant marker for plant height was the same for both growing seasons and panels. This marker on chromosome 4B corresponds to the reduced height (Rht-B1) locus (Chai et al., 2021; Jobson et al., 2019). These results suggest that selection methods can be developed to identify desired characteristics even in segregating populations. As HTP advances, the opportunity to link desired ideotypes (Donald, 1968) expression to single and full plots will allow breeders to implement enhanced selection on all breeding germplasm.

Based on the changing results between the two growing seasons, we examined the effect of G×E within the growing panels. Decomposition of variance revealed that there were large environmental and G×E effects, which could explain the difference observed between years and impede efficient selection decisions. Unfortunately, G×E is a well-known and documented challenge (e.g., De Leon et al., 2016; Elias et al., 2016; Van Eeuwijk et al., 2016) facing plant breeding and effects all stages of plant breeding (Kang, 1997) and evaluation of breeding lines in replicated full plots does not escape the confounding effects of G×E on selection. Even though in our analysis the selection potential has been constrained by G×E, the methods developed may allow for better dissection of G×E. In addition, given the small spatial scale of single plants known, repeated check lines could be included to provide an evaluation in comparison to best material, which is not feasible in large plots. The HTP data may allow plant breeders to better quantify plant growth and environmental conditions providing selection and modeling opportunities to understand plant growth (De Leon et al., 2016).

Within wheat breeding HTP methodology applied in early generations could provide breeding programs with five or more rounds of selection before material is widely tested. The use of pipelined analysis should allow trait extraction to be automated with minimal user intervention and time commitment. At these early stages of the plant breeding program, large investments in time and resources is challenging. This study has focused on wheat and wheat breeding applications, yet these methods should be applicable to a wide range of crops. For example, crops that are clonally propagated such as potato could benefit through individual analysis (Slater et al., 2017). An intermediate wheatgrass (Thinopyrum intermedium) breeding program that uses genomic selection could also complement their selection strategy by combining HTP data increasing selection strategy in a perennial crop (Crain et al., 2021b). For crops with extremely long growth cycles such as trees, the precision phenotyping could cost effectively increase breeding gains (Alves et al., 2020).

5 CONCLUSIONS

We have provided proof of concept for field-based, single plant phenotyping by modifying existing HTP pipelines. As new advancements further enhance HTP systems, breeders can combine this new data with computational resources for efficient phenotyping of plants ranging from segregating F2 generations to fixed lines. As processing pipelines are further refined, plant breeding programs should be able to utilize HTP methods that scale to the size of the breeding program.
compared to time consuming phenotypic measurements or genotyping that would be infeasible in terms of cost and time for evaluating segregating material. This will greatly increase the amount and precision of data that can be used to drive genetic gain. The methodology utilized in this work should be applicable to a range of different crops and plant breeding programs and allow the development of crops that can meet the world’s food, fiber, and fuel needs.

DATA AVAILABILITY STATEMENT
Phenotypic data, including raw images and analysis scripts are available in the Zenodo Repository [https://doi.org/10.5281/zenodo.6515042]. DNA sequence data from genotypes used in this study is available in NCBI Sequence Read Archive (SRA) (https://www.ncbi.nlm.nih.gov/bioproject/) as BioProject accession number PRJNA764168.

ACKNOWLEDGMENTS
We thank Shuangye Wu and Ethan Faryna for assistance in genotyping. This publication is supported by the EArly-concept Grants for Exploratory Research (EAGER) Grant No. 2019-67013-29008 from the USDA National Institute of Food and Agriculture (NIFA) and is an aligned project with the International Wheat Yield Partnership (Grant No. 2017-67007-25933/project accession no. 1011391). The genomics work was performed on the Beocat Research Cluster at Kansas State University, which is funded in part by NSF grants CNS-1006860, EPS-1006860, EPS-0919443, ACI-1440548, CHE-1726332, and NIH P20GM113109. Contribution no. 22-047-J from the Kansas Agricultural Experiment Station. The authors appreciate the constructive comments of two anonymous reviewers.
