(Dated: June 17, 2022)

Boundary conformal field theory (BCFT) and interface conformal field theory (ICFT) attract attention in the context of the information paradox problem. On this background, we develop the idea of the reflected entropy in BCFT/ICFT. We first introduce the left-right reflected entropy (LRRE) in BCFT and show that its holographic dual is given by the area of the entanglement wedge cross section (EWCS) through AdS/BCFT. We also present how to evaluate the reflected entropy in ICFT. By using this technique, we can show the universal behavior of the reflected entropy in some special classes. Furthermore, we clarify what is the holographic dual of boundary primary correlation functions by using this LRRE/EWCS duality.

I. INTRODUCTION

The entanglement entropy (EE) plays a significant role in quantum information, condensed matter, and quantum gravity [1]. This quantity captures the bipartite entanglement between a subsystem and its complement. The EE is defined by the von-Neumann entropy for the reduced density matrix $\rho_{AB} \equiv \text{tr}_B \rho$. Since the EE is not a local observable, it cannot be calculated by a correlation function with a twist operator. The EE does not provide a new understanding of the island model, which is mainly explored in BCFT [19–21]. Interface CFT (ICFT) is a class of CFTs where two (possibly different) CFTs are connected along an interface [22–24]. The entanglement entropy in ICFT is studied in various (1+1)-d setups [25–29]. If one considers the reflected entropy in BCFT/ICFT, one may have several questions, for example, can we directly extract the entanglement wedge cross section between the subsystem and the island (see FIG. 1)? how can we evaluate the reflected entropy in ICFT? We answer these questions.

There is another motivation to investigate the reflected entropy in BCFT/ICFT. Recent progress on the information paradox problem is provided in a class of toy models where the black hole and a non-gravitational bath CFT are glued along the (asymptotic) boundary, which is called the island model [30–32]. This model is related to BCFT/ICFT through the AdS/BCFT and the braneworld holography [33–47]. There are several works about the reflected entropy in the island model [17, 48–51]. In this context, our new measure in BCFT and new technique in ICFT have the potential to provide a new understanding of the island model.

II. LEFT-RIGHT MUTUAL INFORMATION

The left-right entanglement entropy (LREE) is defined by a reduced density matrix obtained by tracing over the right moving sector [19–21].

$$S^{(l/r)} = -\text{tr}(\rho^{(l)} \log \rho^{(l)}),$$  \hspace{1cm} (1)

where $\rho^{(L)} \equiv \text{tr}_R \rho$. One can generalize this quantity by considering a reduced density matrix obtained by tracing over the right moving sector and a part of the left moving sector, as in [19–21].

$$S^{(L)}(A) \equiv -\text{tr}(\rho^{(L)}_A \log \rho^{(L)}_A),$$  \hspace{1cm} (2)

where $\rho^{(L)}_A \equiv \text{tr}_{A,R} \rho$. This quantity can be calculated by the replica trick in the same way as in [19–21]. One can also calculate it by a correlation function with chiral twist operators [52]. With this quantity, one can introduce an interesting quantum information quantity, which we call the left-right mutual information (LRMI),

$$I^{(l/r)}(A) \equiv S^{(L)}(A) + S^{(R)}(A) - S(A).$$  \hspace{1cm} (3)

The physical interpretation is in the following. Let us consider a local excitation that creates a pair of left and right movers. The LRMI increases if both of them are included in the subsystem $A$. That is, the LRMI counts the number of such pairs (see FIG. 1).

In CFTs with time-like boundary, the LRMI has a nice picture. Let us consider the LRMI on a half-plane $\mathbb{R} \times 0$ (see the left of FIG. 2). In a similar way to the state-operator correspondence, a conformal boundary can be described by a linear combination of the Ishibashi states [18].

$$|B\rangle = \sum_i b_i |i\rangle.$$  \hspace{1cm} (4)
The explicit form of the Ishibashi state is

\[ |i\rangle = \sum_N |i; N\rangle \otimes U|i; N\rangle, \]

where \(|i; N\rangle\) is a state in the Verma module \(i\) labeled by \(N\), and \(U\) is an anti-unitary operator. By unfolding the Ishibashi states (which we will denote by \(|\hat{d}\rangle \equiv \sum_N |i; N\rangle \otimes U|i; N\rangle\)), we obtain an interface-like CFT where the interface-like operator \(I(B) = \sum b_i |\hat{d}\rangle\) inserted along the line \(z = 0\) (see the right of FIG. 2). In this picture, the LRMI is just the mutual information between \(A_1\) and \(A_2\) \((A_1\) is defined in the right of FIG. 2) in this interface-like CFT.

For the later use, we first show the calculation of the LREE for the whole system in our language. The LREE for a system in a strip with size \(L\) can be evaluated by the boundary primary correlator with two chiral twist operators,

\[ S^{(l/r)} = \lim_{n \to 1} \frac{1}{1-n} \log \frac{\langle \sigma_n^b(0) \bar{\sigma}_n^b(L) \rangle_{\text{strip}}}{\langle \bar{\sigma}_n^b(0) \bar{\sigma}_n^b(L) \rangle_{\text{strip}}}, \]

where we denote the boundary primary by the superscript \(b\). The coefficient of the two-point function can be evaluated by the conformal map to a cylinder [20] as

\[ \alpha_{ij}^b = \frac{1}{\pi} \left( \sum |b_i|^2 S_{ij} \right), \]

where \(S_{ij}\) is the modular \(S\) matrix and \(h_n\) is the conformal dimension of the twist operator \(h_n \equiv \frac{c}{2\pi} \left( n - \frac{1}{2} \right)\). While one sometimes includes the cutoff parameter \(\epsilon^{2h_n}\) into the coefficient, we split this contribution from the coefficient in this article. For example, in a diagonal RCFT, we obtain

\[ S^{(l/r)} = \frac{c}{6} \log \frac{L}{c} - \left( \sum_i S_{ii}^2 \log \frac{S_{ii}^2}{S_{ii}} \right), \]

where we label the Cardy state by \(a\). The constant term is called the topological entanglement entropy. For special boundary states, the same constant term can also be found in \((2+1)-d\) TQFTs as the topological entanglement entropy [20].

Let us move on to the LREE for a subsystem \(A = [a, b]\), that is, the LRMI. Except for some special models, the calculation of the LRMI is difficult. To show a concrete calculation of the LRMI, we focus on the holographic CFT. The entropy \(S(A)\) can be evaluated by a correlation function of four chiral twist operators with the interface-like operator \(I(B)\),

\[ \langle \bar{\sigma}_n^b(z_1) \sigma_n^b(z_2) I(B) \sigma_n^b(z_1) \bar{\sigma}_n^b(z_2) \rangle. \]

This correlation function can be expanded as

\[ g^n \sum_P C_{\sigma_n}^P \mathcal{F}_P^{v/r} (1 - z), \]

where the sum runs over boundary primaries and \(\mathcal{F}_P^{v/r} (z)\) is the Virasoro block with the cross ratio \(z \equiv \frac{\bar{z}_{23}}{\bar{z}_{12}}\). The \(g\)-function represents a disk partition function [34]. In this holographic CFT, the sum can be approximated by just the vacuum block if \(z\) is enough large. The bulk-boundary OPE coefficient \(C_{\sigma_n}^P\) can be evaluated by the unwrapping procedure [34]. Note that the unwrapping procedure does not change the profile of the boundary [34]. The entropy \(S_A^{(l)}\) is completely fixed by the conformal symmetry. As a result, we obtain

\[ I^{(l/r)}(A) = \max \left( \frac{c}{6} \log \frac{(b - a)^2}{4ab} - 2 \log g, 0 \right). \]

The trivial case, \(I^{(l/r)}(A) = 0\), is given by the vacuum block approximation of the dual-channel.

**III. LEFT-RIGHT REFLECTED ENTROPY**

In a similar way to the LRMI, one can introduce another related quantity, left-right reflected entropy (LRRE), which is a generalization of reflected entropy introduced in [21] (a similar notion was introduced in Chern-Simons theories [11]). To define the LRRE, we consider a canonical purification of a state.
\(\rho_A\) in a doubled Hilbert space \(H_A \otimes H_A^*\). The LRRE is defined by the reduced density matrix obtained from the purified state \(|\sqrt{\rho_A}\rangle\) by tracing over the right moving sector,
\[
S_{R}^{(l/r)}(A) \equiv -\text{tr}\rho_{AA^*}^{(L)}\log \rho_{AA^*}^{(L)},
\]
where \(\rho_{AA^*}^{(L)}\) is the reduced density matrix of \(\rho_{AA^*} = |\sqrt{\rho_A}\rangle \langle \sqrt{\rho_A}|\) after tracing over the right moving sector. The physical interpretation of the LRRE is similar to the LRMI. For example, if one evaluates the LRRE in an integrable system, the LRRE behaves in the same way as the LRMI shown in FIG.\[\text{1}\]. Nevertheless, if one focuses on a non-equilibrium process in a chaotic system where the quasi-particle picture breaks down, the LRRE shows a behavior different from the LRMI (see \[\text{3}\]-\[\text{6}\]).

Let us focus on CFTs with time-like boundary at \(z = 0\). To calculate the LRRE, we can employ the replica trick in the path integral formalism as in [56]. In the same way as the LRMI, we define the corresponding replica manifold in BCFTs by unfolding (see FIG.\[\text{2}\]). This replica manifold is shown in FIG.\[\text{3}\]. The reflected entropy can be evaluated by the partition function on this replica manifold \(Z_{n,m}\) as
\[
S_{R}^{(l/r)}(A) = \lim_{n,m \to 1} \frac{1}{1 - n} \log \frac{Z_{n,m}}{(Z_{1,m})^n},
\]
where the analytic continuation \(m \to 1\) is taken for even integer \(m\). In a similar way to [2], this replica partition function can be re-expressed as a correlation function with four chiral twist operators,
\[
Z_{n,m} = \langle \sigma_{gA}(-b)\sigma_{gA}(-a)I(B)\sigma_{gB}(a)\sigma_{gB}(b) \rangle_{\text{CFT}^\otimes mn},
\]
where we take the interval \(B = [a, b]\) and its mirror \(A = [-b, -a]\). For the same reason as \[\text{9}\], the correlation function includes the interface-like operator. To avoid unnecessary technicalities, we do not show the precise definition of the twist operators \(\sigma_{gA}\) and \(\sigma_{gB}\) (see \[\text{2}\]) because in this article, we only use the conformal dimension of the twist operators,
\[
h_{\sigma_{gA}} = h_{\sigma_{gB}} = h_{\sigma_{gA}^{-1}} = h_{\sigma_{gB}^{-1}} = cn/24 = (m - 1)/m = nh_m,
\]
\[
h_{\sigma_{gA}^{-1}g_B} = h_{\sigma_{gB}^{-1}g_A} = c/12 = n - 1/n = 2h_n,
\]
where \(h_{\sigma_{gA}^{-1}g_B}\) appears as the conformal dimension of the lowest primary operator in the OPE between \(\sigma_{gA}^{-1}\) and \(\sigma_{gB}\). \(\sigma_{gA}^{-1}\) and \(\sigma_{gB}\).

The reflected entropy has a nice bulk interpretation. One can show that the reflected entropy is dual to the area of the entanglement wedge cross section, \(S_R = 2E_W\) [2]. In a similar way, one can find the holographic dual of the LRRE. In the holographic CFT, the correlation function \(\langle 14 \rangle\) in the limits \(n \to 1\) and \(m \to 1\) can be approximated by a single Virasoro block \(F^{W}(2h_n|1-z)\) if \(\epsilon\) is enough large and then we have
\[
\frac{Z_{n,m}}{(Z_{1,m})^n} = C^2_{\sigma_{gA}^{-1}\sigma_{gB}\sigma_{\perp}^{h}} \left(1 + \sqrt{\frac{2}{1-z}}\right)^{-4h_n}.
\]

The OPE coefficient \(C_{\sigma_{gA}^{-1}\sigma_{gB}\sigma_{\perp}^{h}}\) can be evaluated by the unwrapping trick [54] (see also [2]). Since the unwrapping procedure does not affect the interface, we have
\[
C_{\sigma_{gA}^{-1}\sigma_{gB}\sigma_{\perp}^{h}} = (2m)^{-4h_n} \alpha_{\sigma_n},
\]
where \(\alpha_{\sigma_n}\) is defined in (7). The reason why we obtain the coefficient \(\alpha_{\sigma_n}\) is explained in FIG.\[\text{4}\]. Thus, the reflected entropy is given by
\[
S_{R}^{(l/r)}(A) = \frac{c}{3} \log \left(\frac{b}{a}\right) + \text{const.},
\]
which completely matches twice the area of the entanglement wedge cross section defined in FIG.\[\text{5}\] up to constant. In a sim-
ilar way, one can also evaluate the LRRE in the limit of the adjacent intervals $1 - z = \frac{4ab}{(a+b)^2} \ll 1$. For example, the LRRE for the Cardy state $|\alpha \rangle$ in a diagonal RCFT in this limit is given by

$$S_R^{(l/r)}(A) \to \frac{c}{6} \log \frac{(a + b)^2}{ab} - 2 \left( \sum_i S_{ai}^2 \log \frac{S_{ai}^2}{S_{0i}^2} \right). \quad (19)$$

The second term comes from the coefficient $\alpha_{\sigma_{n}}$ in $[17]$. The second term is equal to twice the LRRE $(8)$, which is consistent with the fact $S_R(A, A) = 2S(A)$. In the limit of the adjacent intervals, one can find that the Markov gap $[17]$ has the following form,

$$S_R^{(l/r)}(A) - I_R^{(l/r)}(A) = \frac{c}{3} \log 2 \cdot \cdots \cdot. \quad (20)$$

This universal term can also be found in a special tripartition setup $[15]$. The additional terms depend on the details of the boundary.

Note that in the holographic CFT, the LRRE for a finite subsystem satisfies the inequality (an analog of $[17]$ in CFTs), which is given by

$$S_R^{(l/r)}(A) - I_R^{(l/r)}(A) \geq \frac{c}{6} \log 2 \times (\text{# of cross section boundaries}). \quad (21)$$

It is claimed that the reflected entropy is more sensitive to multipartite entanglement $[14][15]$. The $O(c)$ difference between the reflected entropy and the mutual information implies that there must be a large amount of tripartite entanglement in our tripartition setup associated with the division of the left/right moving sectors.

**IV. REFLECTED ENTROPY IN INTERFACE CFT**

In a similar way to the LRRE, we can define the reflected entropy in an interface CFT, i.e., $\text{CFT}_1 \otimes \text{CFT}_2$ with central charge $c_1$ and $c_2$ (see our setup in FIG 6),

$$S_R(A, B) = \lim_{n,m \to 1} \frac{1}{1 - n} \log \frac{Z_{n,m}}{(Z_{1,m})^n}. \quad (22)$$

**FIG. 6.** The setup that we consider. The interface is symmetrically located on the two intervals. One can also consider an asymmetric setup for topological interfaces.

where the partition function is expressed in terms of (not chiral) twist operators as

$$Z_{n,m} = \langle \sigma_{g_A}(u_1)\sigma_{g_B}^{-1}(v_1)I(A)\sigma_{g_B}(u_2)\sigma_{g_A}^{-1}(v_2) \rangle_{\text{CFT}^\otimes_{n,m}}, \quad (23)$$

where we take the intervals $A = [u_1, v_1]$ and $B = [u_2, v_2]$ with $u_1 < v_1 < u_2 < v_2$. Since the calculation of the reflected entropy is still difficult in general, we focus on the case where the correlation function is approximated by the single block, as in the holographic CFT or in the limit of the adjacent intervals. In a similar way to the BCFT case, one may approximate the correlation function in the holographic CFT as

$$\frac{Z_{n,m}}{(Z_{1,m})^n} = C_{\sigma_{A^{-1}}\sigma_{B}^b\sigma_{g_A^{-b}g_B^{1}}}^2 \langle \mathcal{F}^{vir}(2h'_n|1-z) \rangle^2, \quad (24)$$

where $h'_n = \frac{c_{A}}{24}(n - \frac{1}{n})[58]$. This is true for topological defects but in general, could not be true. This is because one cannot organize the descendant contributions in the same way as CFT without defects. One thing we can say for sure is that the leading contribution in the limit of the adjacent intervals $z \to 1$ is given by

$$\frac{Z_{n,m}}{(Z_{1,m})^n} = C_{\sigma_{A^{-1}}\sigma_{B}^b\sigma_{g_A^{-b}g_B^{1}}}^2 \langle (1-z)^{2h'_n} \rangle^2. \quad (25)$$

The effective central charge $c_{eff} \in [0, \min(c_1, c_2)]$ depends on a profile of the interface (see [23]). Consequently, the reflected entropy in the limit of the adjacent intervals $1 - z = \frac{4ab}{(a+b)^2} \ll 1$ is given by

$$S_R(A, B) = \frac{c_{eff}}{3} \log \frac{(a + b)^2}{ab} + \text{const.} \quad (26)$$

The OPE coefficient can be obtained by the unwrapping procedure (see FIG 4). For the same reason as the entanglement entropy, it is difficult to evaluate the OPE coefficient (more precisely, an analog of $\alpha_{g_A}$) in generic interface CFTs. Nevertheless, in a specific case, topological interface, we can give
the explicit form of the constant part as

\[-2 \sum_i p_i^A \log \frac{p_i^A}{p_i^|}. \tag{27}\]

The property is defined by \( p_i^A = \left| d_i^A \right|^2 |S_{i0}|^2 / N_{0A}^A \) where \( d_i^A \) is the coefficients of the interface operator \( I(A) = \sum_i d_i^A |i\rangle \). \( N_{0A}^A \) is the multiplicity of the vacuum representation in the closed string sector of the partition function. We denote the trivial (identity) interface operator by \( I \).

In general interfaces, the Markov gap is given by \( \sum_i p_i^A \log 2 \). For its derivation and interpretation.) For topological interfaces, the Markov gap is given by

\[S_R(A, B) - I(A, B) = \frac{c}{3} \log 2 + \cdots. \tag{28}\]

The additional terms \( \cdots \) depend on the details of the interface. This universal term is completely consistent with \([15]\).

In general interfaces, the Markov has a complicated form. We provide further analysis in \([59]\).

Let us focus on the holographic interface. One natural realization of the holographic dual of the interface CFT is given by the so-called Janus solution \([24, 60, 61]\). The entanglement entropy in this holographic interface is evaluated in various setups \([62–64]\). In a similar way to \([62–64]\), the entanglement wedge cross section can be evaluated. In the case considered in \([64]\) (also in \([62, 63]\)), the reflected entropy is given by

\[S_R(A, B) = \frac{2c_{\text{eff}}}{3} \log \left( \frac{b}{a} \right) + \text{const.} \tag{29}\]

The effective central charge is the same as that found in \([63]\).

There is another realization by simply connecting two geometries by a thin brane \([62, 64, 65]\), which is a generalization of the bottom-up AdS/BCFT \([71, 72]\). Although there is limited knowledge about the CFT dual of this model, this model is interesting for two reasons. Unlike the top-down model, the thin-brane model is a minimal gravity dual of ICFT. This is an analog of pure gravity. Another reason comes from the island model \([30, 32]\). One can think of the thin-brane as a gravity theory coupled to a non-gravitational bath CFT, called the braneworld holography \([73]\). Through this holography, one can investigate the island model by the ICFT dual to the thin-brane model. In the thin-brane model, the minimal cross section of the entanglement wedge is given by

\[S_R(A, B) = \frac{2 \min(c_1, c_2)}{3} \log \left( \frac{b}{a} \right) + \text{const.} \tag{30}\]

This form of the reflected entropy is non-trivial as we mentioned below \([24]\). This may strongly constrain the profile of the holographic interface.

\[\text{V. HOLOGRAPHIC DUAL OF BOUNDARY PRIMARY}\]

In this section, we address the issue of what is the bulk dual of boundary primary correlation functions by using the LRRE/ EWCS duality. One possible approach is to investigate the boundary primary two-point function through the bulk-boundary OPE. As we saw in the previous section, the LRRE precisely evaluates the bulk-boundary OPE. It implies that the EWCS in FIGS \([5]\) practically describes the boundary primary correlation. In other words, the holographic dual of the boundary primary correlation is described by the geodesics in the bulk.

At first glance, one may provide some other candidates. One may think that the holographic dual of the boundary primary is localized on the brane. This expectation comes from the double holography, where the gravity localized on the ETW brane corresponds to the boundary of the CFT. If this is true, one may expect that the holographic dual of the boundary primary correlation is localized on the brane. However, looking at the AdS\(_2\) slicing of AdS\(_3\),

\[ds^2 = d\rho^2 + L^2 \cosh^2 \left( \frac{b}{L} \right) d\rho^2, \tag{31}\]

one can obtain

\[S_{R^{(\ell/r)}} = \frac{c}{3} \log \left( \frac{\rho_e}{\ell} \right) \cosh \left( \frac{b}{a} \right) + \text{const.} \tag{32}\]

where \( \frac{\rho_e}{\ell} = \log g \). This cannot match \([18]\) even up to constant. One may also consider the EWCS outside the ETW brane, whose intuition comes from the relation between BCFT and ICFT \([70]\). But this breaks the inequality \( S_R \geq I \). Consequently, we propose that the holographic dual of the boundary primary correlation is given by the geodesics in the bulk (not localized on the ETW brane).

\[\text{VI. DISCUSSIONS}\]

In this article, we develop the idea of reflected entropy in BCFT/ICFT. We propose some remaining questions and interesting future works. It would be interesting to investigate the reflected entropy in various setups with boundaries or interfaces, which would tell us about the multipartite entanglement between bulk and boundary/interface. In the holographic CFT, one can explicitly evaluate the reflected entropy in BCFT/ICFT, which has the potential to identify the profile of the holographic interface in the CFT language. An interesting future work is to apply our analysis to the island model, which is essentially a special class of BCFT/ICFT. From such an analysis, one may be able to understand the multipartite entanglement structure of the island model. It is known that the LREE in \((1+1)-d\) CFT has a nice interpretation in \((2+1)-d\) TQFT \([11, 20, 74]\). It would be interesting to find the TQFT picture of the LRRE.
