We demonstrate that a necessary precondition for unconditionally secure quantum key distribution is that sender and receiver can use the available measurement results to prove the presence of entanglement in a quantum state that is effectively distributed between them. One can thus systematically search for entanglement using the class of entanglement witness operators that can be constructed from the observed data. We apply such analysis to two well-known quantum key distribution protocols, namely the 4-state protocol and the 6-state protocol. As a special case, we show that, for some asymmetric error patterns, the presence of entanglement can be proven even for error rates above 25% (4-state protocol) and 33% (6-state protocol).

PACS numbers:

Quantum key distribution (QKD) allows two parties (Alice and Bob) to generate a secret key despite the computational and technological power of an eavesdropper (Eve), who interferes with the signals. Together with the Vernam cipher, QKD can be used for unconditionally secure communication.

QKD protocols distinguish typically two phases to establish a key. In the first phase, an effective bi-partite quantum mechanical state is distributed between the legitimate users, which establishes correlations between them. A (restricted) set of measurements is used to measure these correlations, and the measurement results are described by a joint probability distribution $P(A,B)$. In the second phase, called key distillation, Alice and Bob use an authenticated public channel to process the correlated data in order to obtain a secret key. This procedure involves, typically, postselection of data, error correction to reconcile the data, and privacy amplification to decouple the data from a possible eavesdropper.

In this Letter we consider the first phase of QKD and demonstrate that a necessary precondition for successful key distillation is that Alice and Bob can detect the presence of entanglement in a quantum state that is effectively distributed between them. Such detection may involve available observed data only; it can be realized by using the class of entanglement witness operators that can be constructed from these data.

Two types of schemes are typically used to create correlated data. In prepare&measure schemes (P&M schemes) Alice prepares a random sequence of pre-defined non-orthogonal states that are sent to Bob through an untrusted channel (controlled by Eve). Generalizing the ideas of Bennett et al., the signal preparation can be thought of as follows: Alice prepares an entangled bi-partite state of the form $|\Psi_{\text{source}}\rangle_{AB} = \sum_i \sqrt{p_i} |\psi_i\rangle^A |\varphi_i\rangle^B$. If she measures the first system in the canonical orthonormal basis $|\psi_i\rangle^A$ she effectively prepares the (non-orthogonal) signal states $|\varphi_i\rangle^B$ with probabilities $p_i$. The action of the quantum channel on the state $|\Psi_{\text{source}}\rangle_{AB}$ leads to an effective bi-partite state shared by Alice and Bob. One important characteristic of the P&M schemes is that the reduced density matrix $\rho_A$ of Alice is fixed. In entanglement based schemes a bi-partite state is distributed to Alice and Bob by an, in general, untrusted third party. This party may be an eavesdropper who is in possession of a third sub-system that may be entangled with those given to Alice and Bob. While the sub-systems measured by Alice and Bob result in correlations described by $P(A,B)$, Eve can use her subsystem to obtain information about the data of the legitimate users.

Entanglement based schemes have been introduced by Ekert, who proposed to detect the presence of correlations of quantum mechanical nature by looking at possible violations of Bell-like inequalities. This is, in general, more restrictive than detection of the presence of entanglement. As we will show below, the success of the key distillation phase requires that the performed measurements together with $P(A,B)$ suffice to prove that the (effective) bi-partite state is entangled.

The starting point for our considerations is an upper bound for the distillation rate of a secret key from the correlated data via public communication, which is given by the intrinsic information $I(A;B \downarrow E)$, introduced by Maurer. Consider all possible tri-partite states that Eve can establish using her eavesdropping method, and all measurements she could perform on her sub-system. This gives rise to a set of possible extension $P$ of the observable probability distribution $P(A,B)$ to $P(A,B,E)$. Maurer defines $I(A;B \downarrow E)$ using the mutual information $I(A;B|E)$ between Alice and Bob given the public announcement of Eve’s data, as described by the conditional probabilites $P(A,B|E)$. In an adaptation of Maurer’s work we define the intrinsic information as

$$I(A;B \downarrow E) = \inf_P I(A;B|E).$$

An important consequence is that whenever the observable data $P(A,B)$ can be explained as coming from a tripartite state with a separable reduced density matrix
for Alice and Bob, the intrinsic information vanishes.

**Observation 1** Assume that the observable joint probability distribution \( P(A,B) \) together with the knowledge of the corresponding measurements can be interpreted as coming from a separable state \( \sigma_{AB} \). Then the intrinsic information vanishes and no secret key can be distilled via public communication from the correlated data.

This is easy to see for entanglement based schemes as we extend a separable reduced density matrix \( \sigma_{AB} = \sum_i q_i |\varphi_i\rangle_A \langle \varphi_i| \otimes (|\Phi_i\rangle_B \langle \Phi_i|) \) to a tripartite pure state of the form \( |\Psi_{sep}\rangle = \sum_i \sqrt{q_i} |\varphi_i\rangle_A |\Phi_i\rangle_B |e_i\rangle_E \). Here \( |e_i\rangle_E \) is a set of orthonormal vectors spanning a Hilbert space of sufficient dimension. If Eve measures her sub-system in the corresponding basis, the conditional probability distribution conditioned on her measurement result factorizes so that for this measurement \( I(A:B|E)=0 \). As a consequence, the intrinsic information vanishes and no secret key can be distilled. In the case of P&K&M schemes we need to show additionally that the state \( |\Psi_{sep}\rangle \) can be obtained by Eve by interaction with Bob’s system only. In the Schmidt decomposition \( |\Psi_{source}\rangle \) can be written as \( |\Psi_{source}\rangle = \sum_i c_i |u_i\rangle_A |v_i\rangle_B \). Then the Schmidt decomposition of \( |\Psi_{sep}\rangle \), with respect of system \( A \) and the composite system \( BE \), is of the form \( |\Psi_{sep}\rangle = \sum_i c_i |u_i\rangle_A |e_i\rangle_{BE} \). Since \( c_i \) and \( |u_i\rangle_A \) are fixed by the known reduced density matrix \( \rho_A \) to the corresponding values of \( |\Psi_{source}\rangle \). Then one can find a suitable unitary operator \( U_{BE} \) such that \( |e_i\rangle_{BE} = U_{BE} |v_i\rangle_B |0\rangle_E \) where \( |0\rangle_E \) is an initial state of an auxiliary system.

In both types of schemes it is clear that we can obtain a secret key whenever the distributed (or effectively distributed) bi-partite states are entangled qubit states and we are allowed to perform joint quantum manipulations on these states. This is true since one can distill maximally entangled states in this situation \( 2, 11 \). However, up to now it is not clear whether this is still true if Alice and Bob perform their respective measurements and can perform only classical operations on their correlated data. This scenario has been partially addressed under extra assumptions in \( 11, 12, 13 \). More recently, Acín et al. \( 14 \) proved that one can always distill a secret key from any bi-partite entangled qubit states by adapting the local measurements to the quantum state and performing subsequently a classical protocol.

Let us now turn to the investigation of the correlations in detail. The question whether the effectively distributed bi-partite state is entangled can be addressed based on the ideas of entanglement witnesses. An entanglement witness is an observable that detects the presence of entanglement (if any) of a given state \( \rho \). A state \( \rho \) is entangled iff there exist a hermitian witness operator \( W \) such that \( \text{Tr}(W \rho) < 0 \), while we have \( \text{Tr}(W \sigma) \geq 0 \) for all separable states \( \sigma \). These operators, as any bi-partite hermitian operator, can always be decomposed into a pseudo-mixture of projectors onto product vectors \( W = \sum_i c_i |a_i\rangle\langle a_i| \otimes |b_i\rangle\langle b_i| \), where the coefficients \( c_i \) are real numbers and fulfill \( \sum_i c_i = 1 \). Given such a decomposition of \( W \), the expectation value \( \text{Tr}(W \rho) \) can be obtained directly from the expectation value, \( \text{Tr}(W \sigma) \).

In our approach we consider the reverse problem: Given a particular set of local measurements performed by Alice and Bob, and search for all entanglement witnesses that can be constructed from them.

**Theorem 1** Given a set of local operations with POVM elements \( F_a \otimes G_b \) together with the probability distribution of their occurrence, \( P(A,B) \), then the correlations \( P(A,B) \) cannot lead to a secret key via public communication unless one can prove the presence of entanglement in the (effectively) distributed state via an entanglement witness \( W = \sum_{a,b} c_{a,b} F_a \otimes G_b \) with \( c_{a,b} \) real such that \( \text{Tr}(W \sigma) \geq 0 \) for all separable states \( \sigma \) and \( \sum_{a,b} c_{a,b} F(a,b) < 0 \).

By observation 1 it is a necessary condition for the success of the key distillation phase that we can exclude separable quantum states as the origin of the observed correlations of the first phase. The observed data define equivalence classes of reduced density matrices that are compatible with the data. We need to distinguish between cases where the determined equivalence class contains separable states and those that do not. For this we proceed as follows: Note that the operators of the form \( \sum_{a,b} c_{a,b} F_a \otimes G_b \) form a real vector space which is a sub-space of the vector space spanned by the hermitian operator basis of the composite Hilbert space. The separable density matrices form a compact, convex set in that vector space, and its projection into a sub-space is again a compact and convex set formed by elements that represent the equivalence classes mentioned before. Each element of this new set can be explained as being the projection of a separable density matrix, while the elements of the complement of the set cannot be explained in this way and must therefore come from the projection of an entangled state. In the subspace, we therefore need to distinguish a compact and convex set formed by elements that represent the equivalence classes mentioned before. The corresponding operators on the larger vector space are those witness operators that can be created by real linear combinations of the local measurements. This proves the theorem.

The question whether certain correlations are of quantum origin and might lead to a secure key is therefore reduced to a search over all entanglement witnesses that can be constructed from the protocol and the collected data. We will illustrate the consequences of this view for well-known protocols, namely the 6-state protocol \( 18 \) and the 4-state protocol \( 2 \). In searching through the entanglement witnesses, note that some conditions derived from witnesses are redundant in the sense that all entangled states detected by one witness can be contained
in the set of detected entangled states of another witness. A witness operator $W$ is called optimal if no other entanglement witness exists that detects all states detected by $W$. The class of optimal entanglement witnesses for two qubit states, denoted by OEW, are given by $W = |\phi_e\rangle\langle\phi_e|^T$, where $|\phi_e\rangle$ denotes an entangled state and $^T$ is the partial trace, that is, the transposition with respect to one subsystem.

For the case of the 6-state protocol, Alice and Bob perform projection measurements onto the eigenstates of the three Pauli operators $\sigma_x, \sigma_y, \sigma_z$ in the entangled basis scheme where Eve distributes bi-partite qubit states. In the corresponding P&M scheme, Alice prepares the eigenstates of those operators by performing the same measurements on a maximally entangled qubit state. Therefore, the set of three measurement bases used in the protocol allows Alice and Bob to construct any entanglement witness of the form

$$W = \sum_{i,j=0,x,y,z} c_{ij} \sigma_i \otimes \sigma_j,$$

where $c_0 = 1$ and $c_{ij}$ are real numbers. Note that the set of operators $\{\sigma_i \otimes \sigma_j\}_{i,j}$ constitutes an operator basis in $\mathbb{C}^4 \otimes \mathbb{C}^2$. Therefore Alice and Bob can evaluate all entanglement witnesses, in particular the class OEW of optimal witnesses for two qubits, as given above. This means that in this protocol all entangled states can be detected. Alternatively to the witness approach, Alice and Bob can employ quantum state tomography techniques in connection with the Peres-Horodecki criterion.

While the analysis of the 6-state protocol is quite simple, the 4-state protocol, however, needs a deeper examination since it turns out that the optimal witnesses in OEW cannot be evaluated with the given correlations, as we will see below. In the four state protocol Alice and Bob perform projection measurements in two qubit bases, say $x$ and $z$. In the corresponding P&M scheme Alice uses the same set of measurements on a maximally entangled state.

For the entanglement scheme we obtain the set of entanglement witnesses that can be evaluated with the resulting correlations as

$$W = \sum_{i,j=0,x,y,z} c_{ij} \sigma_i \otimes \sigma_j.$$  \hspace{1cm} (3)

This class, which we shall denote as EW$_4$, can be characterized with the following observation.

**Observation 2** Given an entanglement witness $W$ we find $W \in$ EW$_4$ iff $W = W^T = W^{T^R}$. To see this, we start with the general ansatz of Eqn. (2) and impose the conditions $W = W^T = W^{T^R}$. This directly constraints $W$ to the form (3) since $\sigma_y$ is the only skew-symmetric element in the operator basis. The reverse direction is then trivial.

Note that that the elements of OEW, $W = |\phi_e\rangle\langle\phi_e|^T$, are nonpositive, while $W^{T^R} = |\phi_e\rangle\langle\phi_e|$ is a positive operator for all entangled states $|\phi_e\rangle$. This means that, in contrast to the case of the 6-state protocol, the 4-state protocol does not allow to evaluate the optimal witnesses in OEW. As a result, there can be entangled states that give rise to correlations $P(A, B)$ that are not sufficient to prove the presence of entanglement.

The concept of optimal witnesses can be extended by calling a witness $W$ optimal in class C iff there is no other element in $C$ that detects all entangled states detected by $W$. Our basic goal is now to characterise a family of witness operators that are optimal in class EW$_4$, such that it is sufficient to check this family of witnesses to decide whether the presence of entanglement can be verified from the given data.

For this purpose we present a necessary condition for a bi-partite state to contain entanglement that can be detected by elements of EW$_4$.

**Observation 3** Given $W \in$ EW$_4$, a necessary condition to detect entanglement in state $\rho$ is that the operator $\Omega = \frac{1}{4}(\rho + \rho^{T_A} + \rho^{T_B} + \rho^T)$ is a non-positive operator.

To see this, let us start by the observation that the symmetries of the witness operators in EW$_4$ give rise to the identity $\text{T r}(W\rho) = \text{T r}(W\rho^T)$. Now let us assume that the operator $\Omega$ is non-negative. Then one can interpret it as a density matrix. Since it is invariant under partial transposition, it must be a separable state. Since $W$ is a witness operator, we must therefore find $\text{T r}(W\rho) \geq 0$.

**Theorem 2** Consider the family of operators $W = \frac{1}{2}(Q + Q^T)$, where $Q = |\phi_n\rangle\langle\phi_n|$ and $|\phi_n\rangle$ denotes a real entangled state. The elements of this family are witness operators that are optimal in EW$_4$ and detect all the entangled states that can be detected within EW$_4$.

Let us start by checking that this family, indeed, can detect all entanglement that can be detected in EW$_4$. From the observation 4 we know that we need only to consider bi-partite states $\rho_n$ such that $\Omega_n = \frac{1}{4}(\rho + \rho^{T_A} + \rho^{T_B} + \rho^T)$ is non-positive. We can find, therefore, an (entangled) state $|\phi_n\rangle$ such that $\langle\phi_n|\Omega_n|\phi_n\rangle < 0$. Moreover, since $\Omega_n = \Omega_n^T$, this operator has a real representation. In this representation, also the state $|\phi_n\rangle$ has a real representation. Let us define the projector $Q = |\phi_n\rangle\langle\phi_n|$. Then we find $\langle\phi_n|\Omega_n|\phi_n\rangle = \text{T r}(\frac{1}{4}(Q + Q^{T_A} + Q^{T_B} + Q^T)\rho)$. Therefore, we can define the operator $W = \frac{1}{4}(Q + Q^{T_A} + Q^{T_B} + Q^T)$ that can be further simplified to $W = \frac{1}{4}(Q + Q^{T^R})$ thanks
to the real representation of $Q$. This operator is a witness operator, since $\text{Tr}(W\sigma) \geq 0$ for all separable states $\sigma$, while $\text{Tr}(W\rho_n) < 0$ for the chosen $\rho_n$. Moreover, by construction the family of these witness operators detects all entanglement that can be detected within $\text{EW}_4$. The prove of optimality is omitted here.

The set of witness operators $W = \frac{1}{2}(Q + Q^T)$, with $Q = |\phi_e\rangle\langle\phi_e|$, provides an infinite number of necessary and sufficient conditions for the presence of entanglement in the observable correlations $P(A, B)$. Each condition is characterized by a real entangled state $|\phi_e\rangle$, and therefore the coefficients of the pseudo-mixture decomposition of the corresponding witness operators can be easily parametrized with three real parameters. From a practical point of view, this means that Alice and Bob can easily check this set of conditions numerically.

Let us briefly analyze the implications of our results in the relationship between the bit error rate $e$ in the protocols and the presence of correlations of quantum mechanical nature. Here error rate refers to the sifted key, that is, those events where signal preparation and detection employ the same polarization basis. An intercept/resend attack breaks the entanglement and gives rise to $e \geq 25\%$ (4-state protocol) and $e \geq 33\%$ (6-state protocol), respectively. This means that if the error rate is below these values, this already suffices to prove that the joint probability distribution $P(A, B)$ contains quantum mechanical correlations. However, for some asymmetric error patterns, it is possible to detect the presence of quantum correlations even for error rates above 25% (33%). Let us illustrated this fact with an example that is motivated by the propagation of the polarization state of a single photon in an optical fiber. This channel can be described by a unitary transformation that changes on a timescale much longer than the repetition cycle of the signal source, so it can be thought to be constant over that time. Consider the unitary transformation $U(\theta) = \cos \theta \mathbb{1} - i \sin \theta \sigma_y$. In this scenario, the resulting bit error rate is given by $e = \sin^2 \theta$ and $e = \frac{2}{5} \sin^2 \theta$ for the 4-state and the 6-state protocols, respectively. Nevertheless, in both cases the existence of quantum correlations can be detected for all angles $\theta$. The case of the 6-state protocol is clear, since a unitary transformation preserves the entanglement and all entanglement can be verified in this protocol. With respect to the 4-state protocol, it can also be shown that there is always an entanglement witness $W \in \text{EW}_4$ that detects quantum correlations in $P(A, B)$. In particular, if we select $W_e = \frac{1}{2}(|\phi_e\rangle\langle\phi_e| + |\phi_e\rangle\langle\phi_e|^{T_f})$, with $|\phi_e\rangle$ the eigenvector of the operator $\frac{1}{2}|\psi\rangle\langle\psi|^{T_f}$ ($|\psi\rangle = \cos \theta |00\rangle + \sin \theta |01\rangle - \sin \theta |10\rangle + \cos \theta |11\rangle$) which corresponds to its negative eigenvalue, then we find in a suitable representation as a pseudo-mixture for the entanglement witness that $\text{Tr}(W_e\rho) = \sum_i c_i P(a_i, b_i) = -\frac{1}{4}$.

To conclude, we have as a necessary condition for QKD that the legitimate users can prove the presence of entanglement in the effectively distributed quantum state. In order to construct practical and efficient new QKD protocols, it is vital to separate the generation of two-party correlations from the public discussion protocol which extracts a key from those data. We have analyzed the 4-state and 6-state QKD protocols, and we have derived necessary and sufficient conditions for the existence of quantum correlations in both protocols. As a special case, we have demonstrated that, for some asymmetric error patterns, the presence of this type of correlations can be detected even for error rates above 25% and 33%, respectively.

The authors wish to thank D. Bruß, P. Hyllus, P. van Loock, Ph. Raynal, A. Sanpera, and especially O. Gühne for very useful discussions. This work was supported by the DFG (Emmy Noether programme, SFB 407, SPP 1078), and the network of competence QIP of the state of Bavaria (A8).
