We present a measurement of the first-order azimuthal anisotropy, $v_1$, of deuterons from Au+Au collisions at
One of the main goals of high-energy heavy-ion collision experiments is to explore the state and evolution of nuclear matter under extreme conditions. These experiments measure the multiplicities of many different particle species and the correlations between these particles. The correlations between the azimuthal angles of these particles are particularly informative. The directed flow, $v_1$, and the elliptic flow, $v_2$, are the first and second harmonic coefficients of the Fourier expansion of the particle azimuthal distributions in momentum space relative to the reaction-plane $\Pi$. The reaction-plane is defined by the beam direction and the impact parameter. The directed flow has two components: a rapidity-even function, $v_1^{\text{even}}$, and a rapidity-odd function, $v_1^{\text{odd}}$. The values of $v_1^{\text{even}}$ represent the contribution from event-by-event initial nuclei geometry fluctuations $[2,3]$. This work will focus on the rapidity-odd component. The values of $v_1$ as a function of rapidity, $y$, are sensitive to the amount of expansion the collision system goes through during the early collision stages $[4]$.

The RHIC has completed the first phase of the Beam Energy Scan (BES) program $[5]$. The directed flow $v_1(y)$ as a function of rapidity, $y$, for different mesons and baryons has been measured in Au+Au collisions over the range of beam energies of $\sqrt{s_{NN}} = 7.7$ to 200 GeV $[6,7]$. The slopes $dv_1/dy|_{y=0}$ at mid-rapidity for net-protons and net-$\Lambda$ hyperons as a function of collision energy show a minimum around $\sqrt{s_{NN}} = 10$-20 GeV. According to a hydrodynamic model $[8]$, a minimum $dv_1/dy|_{y=0}$ of net-baryons as a function of collision energy is a signature of a first-order phase transition between hadronic matter and the quark gluon plasma. However, no existing hydrodynamic model can quantitatively reproduce the measured magnitudes of the meson and baryon directed flow $[6,7]$.

Besides the charged hadrons, a large number of light nuclei are produced in heavy-ion collisions. Their production is sensitive to the properties of cluster formation and fireball evolution $[9-13]$. There are two commonly-used and very different phenomenological pictures for the mechanisms governing the production of light nuclei. The thermal model describes deutron production as occurring throughout the whole time evolution of the fireball up to chemical freeze-out via elementary nucleon-nucleon and/or parton-parton interactions $[10,14,15]$. Such models are able to reproduce the observed deuteron multiplicities $[16,17]$. It is, however, difficult to understand how deuterons formed in the intermediate stages of the collisions can survive the subsequent evolution, as their binding energy (2 MeV) is so small compared with the fireball temperature ($\approx 150$ MeV $[18]$). Another model describes deutron production as occurring much later in the collision, near kinetic freeze-out, when the temperatures are much lower $[19-23]$. This is the coalescence model, in which two nucleons that are near each other in space and traveling with similar velocities, can form a deutron. Thus, the momentum distribution of these formed deuterons is strongly related to that of protons. The comparison of light nucleus directed flow with that of protons can provide additional information to understand the mechanisms involved in light nucleus production in high-energy heavy-ion collisions.

Both the EOS and FOPI collaborations observed energy dependence of the directed flow for protons and deuterons from Au+Au collisions for lab kinetic energies of 0.1 A GeV to 1.5 A GeV $[24-26]$. These observations suggest that the directed flow of deuterons has a more pronounced energy dependence than that of protons. Thus, the light nucleus directed flow may provide a more sensitive measure of the collective motion than the lighter hadrons.

In this paper, we present the measurement of the directed flow for deuterons in Au+Au collisions at $\sqrt{s_{NN}} = 7.7$, 11.5, 14.5, 19.6, 27, and 39 GeV from the STAR experiment. The results are discussed and compared with AMPT (A Multi-Phase Transport) calculation $[27]$ and a simple coalescence model $[28]$.

### II. EXPERIMENT AND DATA ANALYSIS

The data used here are for Au+Au collisions at beam energies of $\sqrt{s_{NN}} = 7.7$, 11.5, 14.5, 19.6, 27, and 39 GeV collected by the STAR experiment $[29]$ at the RHIC facility. A minimum bias trigger was used. The 7.7, 11.5, and 39 GeV data were recorded in 2010. The 19.6 and 27 GeV data were recorded in 2011, and the 14.5 GeV data were recorded in 2014. The STAR experiment consists of a solenoidal magnet and different detectors for tracking, triggering, and particle identification (PID). The Time Projection Chamber (TPC) $[30]$ is a charged-particle tracking device which covers the full azimuth and a pseudo-rapidity range $|\eta| < 1$. Charged particle trajectories are reconstructed with the TPC, and the momentum components are obtained from the curvature of the helical path in the 0.5 Tesla magnetic field. The two momentum components in the plane transverse to the beamline define the azimuthal angle of each track. The main detectors used for PID are the TPC and the Time-of-Flight system (TOF) $[31]$. The details of other STAR detectors are described elsewhere $[29]$.
A. Event and Track Selection

For each event, the location of the primary vertex can be reconstructed in three dimensions by extrapolating the TPC track segments to the beam-axis. The primary vertex is required to be within certain distances of the center of STAR in the directions along the beam axis, $v_z$, and transverse to it, $v_r$, as listed in Table I.

TABLE I. The event selection quality cuts $v_z$ and $v_r$ (see text), the number of events, and the baryon chemical potential, $\mu_B$ [32], at each of the different collision energies studied here. The center of transverse radial position is located at $(v_x, v_y) = (0, -0.89 \text{ cm})$ for 14.5 GeV.

| $\sqrt{s_{NN}}$ (GeV) | $v_z$ (cm) | $v_r$ (cm) | Events ($\times 10^4$) | $\mu_B$ (MeV) |
|-----------------------|------------|------------|------------------------|---------------|
| 7.7                   | 70         | 2          | 4                      | 420           |
| 11.5                  | 50         | 2          | 12                     | 315           |
| 14.5                  | 50         | 1          | 11                     | 260           |
| 19.6                  | 50         | 2          | 36                     | 205           |
| 27                    | 50         | 2          | 70                     | 155           |
| 39                    | 40         | 2          | 130                    | 115           |

The reconstructed tracks used in this analysis were required to pass basic quality cuts, including having at least 15 TPC space points assigned to them. Each track is also required to extrapolate to within 1 cm of the primary vertex location (distance of closest approach DCA), and has assigned to it at least half of the possible number of TPC space points (maximum 45) for its trajectory.

The centrality of each event is determined by comparing the charged particle multiplicity measured in the event to a Monte-Carlo Glauber reference [33]. The results presented in this paper use the 10-40% intermediate centrality region ($v_t$, as listed in Table I).

B. Particle Identification

We use a combination of the TPC and the TOF for the identification of charged particles. Figure 1(a) shows the average $dE/dx$ distribution of measured charged tracks versus momentum at $\sqrt{s_{NN}} = 19.6$ GeV. The curves denote the Bichsel expectation values, $\langle dE/dx_B \rangle$, for each species [34].

For each track, the particle speed divided by the speed of light, $\beta = v/c$, can be measured by the combination of the TPC and TOF systems. The TOF thus provides a measurement of the track mass-squared, $m^2$, according to

$$m^2 = p^2 \left( \frac{1}{\beta^2} - 1 \right),$$

where $p$ is the track momentum measured in the TPC. Figure 1(b) shows the $m^2$ distribution as a function of momentum at $\sqrt{s_{NN}} = 19.6$ GeV. For the deuteron selection, the mass-squared values are required to be in the range $3.0 \text{ GeV}^2/c^4 < m^2 < 4.0 \text{ GeV}^2/c^4$.

The selection of deuteron tracks using the TPC $\langle dE/dx \rangle$ proceeds via the variable $z$, defined as [35],

$$z = \ln \left( \frac{\langle dE/dx \rangle}{\langle dE/dx_B \rangle} \right).$$

When using the Bichsel prediction, $\langle dE/dx_B \rangle$, for deuterons in Eq. 2(cf. Fig. 1), the deuterons are those tracks with values of $z$ near zero. Figure 2 shows the $z$ distributions in different $p_T$ ranges at $\sqrt{s_{NN}} = 19.6$ GeV. In this analysis, the deuteron selection involves the requirement that $|z| < 0.2$.

FIG. 1. (a) The $\langle dE/dx \rangle$ of charged tracks versus momentum in Au+Au collisions at $\sqrt{s_{NN}} = 19.6$ GeV. The curves are Bichsel predictions for the corresponding particle species. (b) Particle $m^2$ versus momentum at $\sqrt{s_{NN}} = 19.6$ GeV. The bands, from bottom to top, correspond to $\pi^+$, $K^+$, protons, and deuterons, respectively.

FIG. 2. The $z$ distribution for deuteron in various $p_T$ ranges in Au+Au collisions at $\sqrt{s_{NN}} = 19.6$ GeV. The dashed line is a Gaussian fit representing the distribution for deuterons. The dot-dashed curve is a Gaussian fit denoting contributions from $\pi^+$, $K^+$, and protons.

In Ref. [6], the $v_1(y)$ of protons was measured over the range of 0.4 GeV/$c < p_T < 2.0$ GeV/$c$. For the deuterons in...
this analysis, the transverse momentum range is restricted to the same range in terms of $pT/A$, or $0.8 \text{ GeV}/c < pT < 4.0 \text{ GeV}/c$. The default rapidity window for extracting the $v_1(y)$ slope is $|y| < 0.6$.

C. Event Plane

The reaction-plane angle, $\Psi_R$, is the azimuth of the plane spanned by the beam direction and the impact parameter vector. The $v_1$ of the produced particles with respect to $\Psi_R$ can be measured as $v_1 = \langle \cos(\phi - \Psi_R) \rangle$, where $\phi$ is the azimuthal angle of the produced particle and the angle brackets imply averaging over all the particles in all events. As the reaction-plane angle, $\Psi_R$, cannot be measured directly, we will use the event-plane angle $\Pi_1$ to estimate the reaction-plane angle $\Psi_R$. The event-plane was estimated using the $v_1$ information of the final-state particles, and hence is called the first-order event-plane ($\Psi_1$). The self-correlations were eliminated with the large acceptance gap between the TPC, where the deuterons directed flow was measured, and the detectors measuring the large acceptance gap between the TPC, where the deuteron is called the first-order reaction-plane angle, $\Psi_1$.

Two beam-beam counters (BBCs) were used to reconstruct the values of $\Psi_1$. The distribution of reconstructed $\Psi_1$ values is not uniform due to imperfections in the BBCs. Therefore, a shifting method was applied to flatten the distributions. The finite multiplicity of particles in each event limits the precision of estimating the true reaction-plane via the reconstructed $\Psi_1$, so the values of $v_1$ have been corrected for the event plane resolution: $v_1 = \langle \cos(\phi - \Psi_1) \rangle/R_1$. The resolution correction factor, $R_1$, is determined by the sub-event plane correlation method [1], where the sub-event planes are reconstructed separately in the east and west BBCs. Figure 3 shows the $R_1$ values as a function of the collision centrality at each collision energy. The resolution peaks in mid-central collisions. The resolution improves as the collision energy decreases due to the stronger directed flow at the rapidity ranges covered by the BBC detectors.

D. Systematic Uncertainties

The systematic uncertainties on the directed flow are estimated by varying the criteria used to select tracks and identify particles. The absolute difference between the results using the default and the varied criteria is quoted as the systematic uncertainty. The systematic uncertainty related to the track selection procedure is estimated by varying the DCA (from 1 to 0.5 and 2 cm) and the number of TPC space points (from 15 to 20). The value is found to be about 6% and independent of the particle species. Additional systematic uncertainties arising from the particle misidentification are estimated by varying the PID cuts on $z$ and $m^2$. The typical magnitudes of these uncertainties are 4% for protons and 15% for deuterons. The systematic uncertainty corresponding to the chosen range of the $dv_1/dy$ fit is estimated by taking the difference between the best fitted slope, and the value of the slope within $|y| < 0.5$. This uncertainty is about 6% at $\sqrt{S_{NN}} = 7.7$ GeV. It is the choice of the $dv_1/dy$ fit range that makes the largest contribution to the total systematic uncertainties above 7.7 GeV. Non-flow contributions to the systematic uncertainty are reduced due to the large pseudo-rapidity gap between the TPC and BBC detectors. The event-plane resolution is estimated via the correlation of the event-planes calculated for two sub-events, which can be affected by momentum conservation [37]. The possible systematic uncertainty from the first-order event-plane resolution estimation is discussed in Ref. [6]. The uncertainty is less than 2%. All the sources are added in quadrature as the final total systematic uncertainties, which are of a similar magnitude as the statistical uncertainties.

III. RESULTS AND DISCUSSION

Figure 4 shows the rapidity dependence of the directed flow, $v_1$, of protons and deuterons at each of the studied collision energies. The $v_1(y)$ of deuterons is antisymmetric about $y = 0$. As with the protons, the $v_1(y)$ of deuterons increases monotonically with increasing rapidity at $\sqrt{S_{NN}} = 7.7$ GeV. We observe a stronger $v_1$ dependence on rapidity for deuterons than for protons. The limited event statistics and relatively lower deuteron production rate at higher energies makes such comparisons less certain.

The $v_1(y)$ slope at mid-rapidity ($y < 0.6$) is obtained by fitting the data with a straight line. For $\sqrt{S_{NN}} > 7.7$ GeV, the sign of the $v_1(y)$ slope is mainly influenced by the two data points at the extreme rapidity bins. Figure 5 presents the resulting values of the $v_1(y)$ slope versus the collision energy for 10-40% central collisions. A significantly larger deuteron $v_1(y)$ slope with respect to protons is observed at $\sqrt{S_{NN}} = 7.7$ GeV. The deuteron $v_1(y)$ slope is observed to
be consistent with zero at all energies above 7.7 GeV, but with large uncertainties.

The results from the data were compared to those from the AMPT model [27]. This is a hybrid model which has been used to describe the charged particle multiplicity, transverse momentum, and the elliptic flow of identified particles in relativistic heavy-ion collisions. In this model, scattering among hadrons is described by ART (A Relativistic Transport) model [38]. The deuterons are produced and dissolved within ART via nuclear reactions. The centrality of the simulated events is determined by integrating the charged particle multiplicity distribution, as was done for the experimental data. The comparison between data and the AMPT model result can be seen in Fig. 5 [27]. A decreasing trend for increasing collision energies is seen in the AMPT simulation, while the model significantly overpredicts the observed magnitude of the deuteron directed flow slope.

A commonly-applied picture for light nucleus production in heavy-ion collisions involves the coalescence of nucleons which are close to each other in space and have similar velocities. Then, the spectral distribution of a light nucleus, \( d^3N_A/d^3p_A \), depends on the distributions of protons, \( d^3N_p/d^3p_p \), and neutrons, \( d^3N_n/d^3p_n \), [21],

\[
E_A \frac{d^3N_A}{d^3p_A} \propto \left( E_p \frac{d^3N_p}{d^3p_p} \right)^Z \left( E_n \frac{d^3N_n}{d^3p_n} \right)^{A-Z},
\]

where \( A \) and \( Z \) are nucleus mass number and charge number, respectively. In this production mechanism, the expected value of the light nucleus directed flow can be expressed as a function of the directed flow of its constituent nucleons. Assuming the protons and neutrons flow similarly, the deuteron \( v_1 \) is given by [28],

\[
v_{1,d}(y_{pt}) = \frac{2v_{1,p}(y_{pt})}{1 + 2v_{1,p}^2(y_{pt})},
\]

where each constituent nucleon has half the \( pt \) and the same rapidity as the deuteron. Then one can calculate the expected \( v_1 \) for the deuterons from the measured \( v_1 \) for protons [27], assuming as usual the (unmeasured) neutron flow is the same as that of the (measured) protons. As the proton \( v_1 \ll 1 \), Eq. 4 can be simplified as

\[
v_{1,d}(y_{pt}) \approx 2v_{1,p}(y_{pt}^2/2).
\]

This indicates that, in the coalescence mechanism, the \( v_1 \) of protons and deuterons will follow an atomic mass-number scaling. In fact, Eq. 4 and Eq. 5 can be applied to any anisotropy coefficient. For the elliptic flow of light nuclei, the STAR collaboration has observed such a mass-number scaling in \( \sqrt{s_{NN}} = 7.7-200 \) GeV Au+Au collisions [39]. The expectation would thus be that the \( v_1(y) \) slope for deuterons would have the same sign as that observed for the protons and have a larger magnitude. In Fig. 5 within the statistical and systematic uncertainties, the deuteron \( v_1(y) \) slope at mid-rapidity is consistent with this expectation at \( \sqrt{s_{NN}} = 7.7 \).
dependence of the directed flow, \( v_1(y) \) of deuterons in Au+Au collisions at \( \sqrt{s_{NN}} = 7.7\)–39 GeV. At 10–40% centrality, the \( v_1(y) \) slope, \( dv_1/dy|_{y=0} \), shows a strong increase at the lowest collision energy of \( \sqrt{s_{NN}} = 7.7 \) GeV, and is consistent with zero for energies above 7.7 GeV. The AMPT transport model significantly overestimates the values of deuteron \( v_1(y) \) slopes at most measured collision energies. The coalescence model for deuteron production predicts an atomic-mass-number scaling of the proton and deuteron \( v_1 \). At \( \sqrt{s_{NN}} = 7.7 \) GeV and 11.5 GeV, this is approximately valid for the \( v_1(p_T) \) data at higher \( p_T \) within \( |y| < 0.6 \), while the \( v_1(p_T) \) show enhancements towards very low \( p_T \) at \( \sqrt{s_{NN}} = 7.7 \) GeV. There is at present no explanation for this enhancement. Stronger conclusions will be possible with the event statistics achieved with the Beam Energy Scan II program.

IV. SUMMARY

In summary, we present the mid-rapidity directed flow \( v_1(y) \) of deuterons in Au+Au collisions at \( \sqrt{s_{NN}} = 7.7\)–39 GeV. At 10–40% centrality, the \( v_1(y) \) slope, \( dv_1/dy|_{y=0} \), shows a strong increase at the lowest collision energy of \( \sqrt{s_{NN}} = 7.7 \) GeV, and is consistent with zero for energies above 7.7 GeV. The AMPT transport model significantly overestimates the values of deuteron \( v_1(y) \) slopes at most measured collision energies. The coalescence model for deuteron production predicts an atomic-mass-number scaling of the proton and deuteron \( v_1 \). At \( \sqrt{s_{NN}} = 7.7 \) GeV and 11.5 GeV, this is approximately valid for the \( v_1(p_T) \) data at higher \( p_T \) within \( |y| < 0.6 \), while the \( v_1(p_T) \) show enhancements towards very low \( p_T \) at \( \sqrt{s_{NN}} = 7.7 \) GeV. There is at present no explanation for this enhancement. Stronger conclusions will be possible with the event statistics achieved with the Beam Energy Scan II program.

ACKNOWLEDGEMENT

We thank the RHIC Operations Group and RCF at BNL, the NERSC Center at LBNL, and the Open Science Grid consortium for providing resources and support. This work was supported in part by the Office of Nuclear Physics within the U.S. DOE Office of Science, the U.S. National Science Foundation, the Ministry of Education and Science of the Russian Federation, National Natural Science Foundation of China, Chinese Academy of Science, the Ministry of Science and Technology of China and the Chinese Ministry of Education, the Higher Education Sprout Project by Ministry of Education at NCKU, the National Research Foundation of Korea, Czech Science Foundation and Ministry of Education, Youth and Sports of the Czech Republic, Hungarian National Research, Development and Innovation Office, New National Excellency Programme of the Hungarian Ministry of Human Capacities, Department of Atomic Energy and Department of Science and Technology of the Government of India, the National Science Centre of Poland, the Ministry of Science, Education and Sports of the Republic of Croatia, RosAtom of Russia and German Bundesministerium fur Bildung, Wissenschaft, Forschung und Technologie (BMBF), Helmholtz Association, Ministry of Education, Culture, Sports, Science, and Technology (MEXT) and Japan Society for the Promotion of Science (JSPS).

FIG. 6. The \( p_T \) dependence of \( v_1/A \) in \( |y| < 0.6 \) for protons (open squares) and deuterons (solid circles) in 10–40% Au+Au collisions at \( \sqrt{s_{NN}} = 7.7 \), 11.5, 14.5, 19.6, 27, and 39 GeV. Statistical uncertainties (bars) and systematic uncertainties (horizontal lines) are shown separately.

GEV. For \( \sqrt{s_{NN}} > 7.7 \) GeV, the deuteron \( v_1(y) \) slopes have a different sign than the corresponding proton \( v_1(y) \) slopes with large uncertainties.

To further test the coalescence model, we studied the \( p_T \) dependence of the directed flow, \( v_1 \), at all measured energies, which is shown in Fig. 6. At \( \sqrt{s_{NN}} = 7.7 \) GeV and 11.5 GeV, the values of \( v_1(p_T) \) indicate a mass-number scaling for \( p_T/A > 1 \) GeV/c within \( |y| < 0.6 \), while the value of the deuteron \( v_1/A \) shows an enhancement towards lower \( p_T/A \) at \( \sqrt{s_{NN}} = 7.7 \) GeV. This enhancement is not caused by the knock-out deuteron background with its negligible production at \( \sqrt{s_{NN}} = 7.7 \) GeV [35].

At forward rapidities, the E877 collaboration observed such an enhancement of the \( v_1(p_T) \) of deuterons, tritons, \(^3\)He, and \(^4\)He at \( p_T < 0.5 \) GeV/c in Au+Au collisions at a beam energy of 10.84 GeV [40]. The cause of the low \( p_T \) enhancement of the deuteron \( v_1 \) in the \( \sqrt{s_{NN}} = 7.7 \) GeV Au+Au collisions is unclear.
