Abstract

In this report we present pulmonary vein and posterior box isolation together with the right superior ganglion plexus ablation using the Qdot Micro catheter without fluoroscopy. We describe different possibilities of this new technology for catheter ablation. The main advantages of this catheter to potentially increase ablation safety and effectiveness are discussed. Specifically, the possibility to perform high-density mapping with the lowest available distance between points. Furthermore, the possibility to decrease the risk of collateral tissue damage and to improve atrial linear lesions contiguity, transmurality and durability due to the dominance of resistive heating supported by the feedback temperature control. Finally, the possibility to shorten the procedure and fluoroscopy duration due to the high shortening of application duration to 4 seconds only.

Keywords: atrial fibrillation · pulmonary vein isolation · high power short duration ablation · Qdot Micro catheter · ganglion plexus ablation · zero-fluoroscopy ablation

Introduction

Isolation of the pulmonary veins is the most effective treatment for atrial fibrillation (AF) [1]. The reference method of this procedure is radiofrequency (RF) ablation with a single-point catheter using an electroanatomical system. Its main limitations are the long duration of the procedure and still unsatisfactory effectiveness [2]. Hence, methods are sought to increase its effectiveness and safety, combined with shortening of the procedure’s duration. One of the ways is to use single-shot devices such as balloons or the pulmonary vein ablation catheter [2-3]. An alternative is to shorten the time of a single application. In part, it was possible to achieve this by controlling the pressure of the electrode against the tissue, especially in combination with the so-called “close” protocol [4]. The next big step seems to be increasing the power to 90W, which allows to shorten a single application to 3-4 seconds. The primary aim of this article is to present the new Qdot catheter, which is the first device to enable this procedure [5].

In recent years, there has been an increased interest in cardioneuroablation [6-10]. A beneficial effect has been demonstrated by this type of procedure for patients with reflex syncope [6-10]. Since in some patients with sinus node disease the syncope is functional (patients with rapid rhythm-induced pauses, drug-induced sinus node disease, athletes with bradyarrhythmia) [11], ablation of the parasympathetic ganglia is often effective for them and allows them to avoid pacemaker implantation [6, 12]. To the best to our knowledge, there have been no studies presenting cardioneuroablation using high-power short-duration ablation. Thus, our second aim is to present the first experience with Qdot+ protocol in pulmonary vein ablation together with cardioneuroablation.

Case presentation

To illustrate these aims, we present the case of a 77-year-old female after the right atrial inferior isthmus ablation because of typical atrial flutter 5 years ago. For about 2 years the patient experienced paroxysmal AF with EHRA score III [1]. The symptoms of arrhythmia consisted of palpitations, chest discomfort, shortness of breath, headache and dizziness. Concealed sinus node disease was also diagnosed (during treatment with a beta-adrenoreceptors an episode of syncope occurred and in 24-hour ECG holter monitoring there were pauses of automatism up to 4 seconds). These symptoms resolved after the discontinuation of antiarrhythmic drugs. The patient reported an episode of gastrointestinal bleeding. Since pharmacotherapy was not possible, the patient was qualified for pulmonary vein isolation together with parasympathetic ganglion plexi ablation. Before the procedure, thromboembolic material in the left atrium was excluded using transesophageal echo. Patent foramen ovale (PFO) was diagnosed with small interatrial leak. Because the transeptal puncture was not necessary, the patient was qualified for ablation without fluoroscopy using the technique we previously described [13].

At the beginning of the procedure the patient was on AF. The catheters were introduced into the coronary sinus and the right ventricle under the control of CARTO system. Using the Qdot catheter, long transeptal sheaths were introduced via the right femoral vein into the superior vena cava. The right atrial voltage map was made using the LassoNav catheter. On its basis, a Qdot catheter was introduced into the left atrium through the PFO. Over this catheter two transseptal sheaths were successively inserted into the left atrium. A map of the left atrium and proximal parts of the pulmonary veins was obtained using the CARTO system. The pulmonary vein potentials were diagnosed in all four pulmonary veins. With the use of the Qdot+ algorithm (90W for 4 s), all pulmonary vein isolation was performed according to the “close” protocol, verified with the LassoNav catheter (Fig. 1-3).

![Fig. 1. One of the RF applications during left pulmonary veins isolation; pressure (the white arrow) of the catheter on the posterior wall is 16g. Bulls’ eye (the yellow arrow) indicate good pararell contact of the catheter tip with the left atrial tissue with optimal temperature increase at the second second of application (red zone in left superior quadrant); green dots – pulmonary vein potentials, pink dots – fragmented potentials, red dots – ablation points; Abl – ablation catheter, CS – catheter in the coronary sinus, LA – the left atrium, LAA – the left atrial appendage, Lasso – LassoNav catheter inside the left inferior pulmonary vein, LIPV – the left inferior pulmonary vein, LSPV – the left superior pulmonary vein, RIPV – the right inferior pulmonary vein, RSPV – the right superior pulmonary vein; panel A – superior view, panel B – posterior view on the left atrium]
At the beginning of the left superior pulmonary vein isolation, the sinus rhythm returned without pathological pause. After pulmonary veins’ isolation the right superior ganglion plexus was mapped using 100 ms cycle length stimulation (mixed type reactions were observed). The pacing induced unsustained atypical atrial flutter. Ablation was performed at ganglionated plexi (GB) stimulation sites, however we did not observe significant acceleration of the sinus rhythm. Because of the small distance between the lines, the posterior segment was isolated (the line in the roof and in the lower part of the posterior wall) (Fig. 4-5). LassoNav catheter mapping was performed with accessory applications to obtain full pulmonary veins and the posterior segment isolation. The post-procedure and follow-up (on the following day) transthoracic echocardiography did not reveal any fluid in the pericardium.

Duration of the procedure was 140 min (puncture and catheter introduction 20 min, right atrial mapping – 10 min, transseptal access – 10 min, left atrial and pulmonary vein mapping – 20 min, left pulmonary vein isolation – 22 min, right pulmonary vein isolation – 33 min, mapping of the right superior GP and its ablation – 10 min, posterior segment isolation – 10 min, control mapping of the pulmonary veins and posterior wall – 5 min). The procedure was performed without the use of fluoroscopy. The total time of 203 RF current applications was 13 min 32 s. After the procedure we observed sinus rhythm 75 bpm, BP 115/70 mmHg. There were no complications. Sinus rhythm was maintained during the postoperative monitoring. On the next day, the patient was discharged home in good general condition. Pharmacotherapy with dabigatran, rosuvastatin and a proton pump inhibitor was maintained. There were no palpitations or syncope during follow-up.

**Discussion**

The Qdot micro catheter is a new generation catheter that offers advantages of the recent technological developments. Below we present all advantages of this catheter.

**Typical thermocool catheter with pressure control**

The design of the Qdot Micro catheter allows it to be used as a typical ablation catheter with a cooled tip and with...
High-power and short-duration ablation with the Qdot+ algorithm for...

High-density mapping

High-density mapping is one of the milestones of modern electrophysiology. It allows for the increase of the precision of arrhythmogenic substrate mapping and thus increases the success rate in complex arrhythmias [14]. There are different technical solutions for high-density mapping. The resolution of this mapping varies with catheters from different brands. For example, the Orion catheter (Boston Scientific) is a foldout rosette consisting of 8 arms. There are 8 small electrodes with an area of 0.4 mm$^2$ spaced 2.5 mm apart (a total of 64 electrodes) on each arm. The electrode is compatible with the Rhythmia system (Boston Scientific) and enables automatic map-making from high density of points (annotation of signals is automatic as it would be impossible to conduct manually). Another example is the Advisor HD-grid (Abbott) high-density mapping catheter cooperating with the EnSite system (Abbott) consisting of 4 electrode strands (1 mm length/width; 3 mm apart) with 4 electrodes each. The distance between the electrodes in both directions is the same, thanks to what we obtain 24 pairs of electrodes for bipolar recordings and 16 electrodes for unipolar recordings. Due to the even distribution, it is possible to evaluate bipolar electrograms in both perpendicular planes. Another example of catheter for high density mapping is the Octarey catheter (Johnson & Johnson) cooperating with CARTO 3 system. This catheter consists of 8 diverging flexible arms containing 6 small electrodes (0.5 mm long) 2 mm apart (48 electrodes in total). Unlike the Qdot micro catheter, all of the above are only mapping catheters and require a separate ablation catheter.

In the Qdot micro catheter three microelectrodes are placed 1.5 mm apart around the distal end of the ablation tip (Fig. 6). The size of the electrodes is 0.32 mm in diameter with a surface area of 0.086 mm$^2$ each. Currently, these catheters were introduced into the left atrium via PFO together with the final left atrial anatomical glass map after pulmonary vein isolation and posterior segment isolation; LAO projection.
are the smallest microelectrodes and the closest spacing between them among the available high-density mapping catheters. The small surface area of the microelectrodes enables discrete, high-resolution signals with less far-field information than the larger ablation tip affords. The microelectrode signals can be displayed as unipolar and bipolar electrograms. The highest voltage electrogram among three microelectrode pairs is used to apply color to the voltage map. The microelectrodes signals do not apply to LAT (local activation time) maps. The bipolar electrograms are displayed as microelectrode pairs: 1-2, 2-3, 3-1. The numbers of the microelectrodes may be displayed on the CARTO 3 map, which can help with the selection of microelectrodes pairs for pacing. Microelectrode pacing may facilitate very local capture and is routed between microelectrode pairs. Pacing is not routed between any microelectrode and a standard electrode. Microelectrodes are more sensitive to power line noise during the RF application than the larger electrodes. The CARTO 3 system employs advanced power line noise filters for exceptional signal quality. This could lead to damage of monitoring during RF current application. When using the Confidense module with continuous mapping feature, the stability filter must be used to prevent acquisition of points during catheter motion.

**High density temperature control (including catheter orientation)**

The predecessor catheter Smarttouch SF employs a single thermocouple in the center of the ablation tip, surrounded by cooling saline. Using this design, the temperature should be monitored only to confirm that the irrigation is adequate (and temperature rise during ablation may indicate blocked irrigation). In the Qdot catheter there are 6 thermocouples placed in the channels within the wall of the distal electrode itself around this electrode in close proximity to the tissue interface (Fig. 7). Three thermocouples are located distally around the catheter tip (0.075 mm from the real tip), and three thermocouples are located proximally around the catheter tip (3 mm from the real tip) (Fig. 6-7).

The CARTO 3 system displays the temperature measured on the catheter, which helps to confirm energy delivery to the tissue and the tip-tissue contact stability (Fig. 1-2). The temperature color display aids in understanding the orientation of the catheter tip to the tissue during RF ablation (Fig. 1-2). Red color centered on the "bulls' eye" indicates that the catheter is touching the tissue in perpendicular orientation (Fig. 2). Red color on one side of the display indicates heating on that side of the ablation tip, which signals that the ablation tip is connecting the tissue in a parallel orientation (Fig. 1).

**Feedback temperature control**

It has been shown that an increase of temperature >85°C is an important risk factor for the so-called steam pop, which may be the cause of cardiac tamponade [15]. To increase the safety of the RF application, the temperature is measured every 33 ms and if it increases above programmed...
value then the power is reduced or saline flow is increased [15]. There are two different modes of feedback control (Fig. 8-9).

When the maximum power of RF current is set for lower or equal 35 W, after activation of the generator, irrigation begins at four milliliters per minute for the pre-determined RF delay period (few seconds). After the onset of RF energy delivery, we begin to see a temperature rise. In this instance the temperature rise is steep and a burst of the higher flow rate (15 mL/min) is automatically applied. When the temperature drops, the irrigation is returned to the lower flow rate (4 mL/min). As the temperature reaches the target (65°C is recommended) there is another burst of the higher irrigation flow rate, until the temperature drops below the target. If the temperature exceeds the target temperature, another burst of the higher flow rate is applied, as well as decrease in the power delivered. When the temperature drops, the power increases again, and the flow rate decreases to the lower rate (Fig. 8).

When the maximum power of RF current is set for > 35 W, the irrigation flow rate starts at 15 mL/min. If the measured temperature does not rise, the irrigation rate drops to 4 mL/min until the temperature exceeds the preset max low flow temperature value. Once the temperature rises above this temperature, the irrigation rate is increased to 15 mL/min. The irrigation rate and the power are automatically adjusted to maintain the temperature between the max low flow and the target value, and the primary means of temperature control is the irrigation flow rate. Power is adjusted if the higher irrigation rate is insufficient to affect a temperature response. If the temperature reaches the pre-determined cut-off temperature level, the RF application will be automatically terminated (Fig. 9).

Fig. 9. Feedback temperature control when the maximum power of RF current is set for lower or equal 35W; description in the main text; panel A – temperature do not reach target level, panel B – temperature reach target level
High power, short duration ablation

The greatest advantage of the Qdot catheter is the ability to perform a high-energy short duration ablation [15-17, 19]. In RF ablation, the tissue damage occurs in two consecutive phases. The first is resistive phase, the second is the conductive phase. The first one depends directly on the amount of energy delivered at the catheter-tissue interface. The second one is mainly contingent on the time of application and results from the gradual passive heating extend to deeper tissue layers. When the temperature reaches 50°C, an irreversible myocardial tissue injury occurs. At lower temperatures, the reversible damage often occurs with accompanying tissue edema [15]. In traditional RF ablations, the second effect dominates. It is difficult to predict when the application is transmural. There is a risk of underheating, which may be masked by the tissue edema (hence the acute effect may be effective and after the edema disappearance, conduction or automatism recurs). Alternatively, the overheating causes damage to neighboring organs. Hence, in order to increase the safety and effectiveness of the radiofrequency current ablation, the concept of high-power short-duration applications was developed [15-17, 19]. When using high power for a few seconds, we observe only the resistive effect. In animal experiments, it was shown that the best efficacy and safety rates was obtained with applications duration of 4 seconds [15-17]. Using the power of 90 W at this duration, the depth of lesion was 3.6±0.6 mm and the width was 10.4±1.2 mm [15]. The variances of these parameters were smaller than after classical applications, which resulted in more frequent continuous lines without the gap both in direct [15-17] observation and after 30 days follow-up [16]. As the thickness of the atrium muscle is comparable to the depth of the lesion [18], no damage to the adjacent organs was also observed [15].

The tissue overheating may result in steam pop which can cause cardiac tamponade. The steam pop was observed in animal models if temperature of the catheter-tissue interface was > 85°C or the catheter pressure was > 40g [15]. To avoid this phenomenon, a feedback temperature control was introduced. Without this protection, the phenomenon of steam pop was noticed during 3/174 applications (1.7%). After the introduction of this algorithm, this phenomenon was not observed during 233 applications. Shortening the time of a single application during the isolation of the right superior pulmonary vein resulted in a reduction in their duration compared to classic procedures in animal studies from 270±60 s to 33±6 s [15].

Qdot procedure in our patient

There is limited experience with PVI isolation using Qdot catheter and high-power and short duration ablation. A single clinical study assessed its feasibility, safety and short-term effectiveness on 52 patients [19]. Direct isolation was achieved for all pulmonary veins including an adenosine/isoproterenol check. The study showed favorable mean procedure and fluoroscopy duration compared to classic ablation. There were 2 complications: a pseudoaneurysm and an asymptomatic cerebral thromboembolism. After 3 months of follow-up, 49 patients (94,2%) had sinus rhythm, whereas 2 had AF and one had atrial flutter. To the best of our knowledge, there is no data about GP ablation using high-power short duration applications. However, all the preclinical data suggest that when using this form of ablation, the damage is transmural. Thus, it should be effective in this kind of ablation.

Conclusion

The Qdot Micro catheter presented in this article offers some new advantages potentially increasing ablation safety and effectiveness. Specifically, the possibility to perform high-density mapping with the lowest available distance between points. Furthermore, the possibility to decrease the risk of collateral tissue damage and to improve atrial linear lesions contiguity, transmurality and durability due to the dominance of resistive heating supported by the feedback temperature control. Finally, the possibility to shorten the procedure and fluoroscopy duration due to the high shortening of application duration to 4 seconds only.
