ABSTRACT

We explore host galaxy properties and environment of a sample of Type 1 and 2 active galactic nuclei (AGN) taken from the COSMOS2015 catalog, within $0.3 \leq z \leq 1.1$ selected for their emission in X-rays, optical spectra and SED signatures. We find different properties of host galaxies of distinct AGNs: Type 1 AGNs reside in blue, star-forming and less massive host galaxies compared to Type 2. The majority of the AGNs have intermediate X-ray luminosities, $10^{42} \leq L_X < 10^{44} \text{ erg s}^{-1}$, while only a few have X-ray luminosities ($L_X > 10^{44} \text{ erg s}^{-1}$) as those observed in QSOs. Non-parametric morphological analysis show that the majority of Type 1 AGN hosts are elliptical or compact galaxies, while Type 2 AGN host present more scatter, from spirals, irregulars and elliptical galaxies. The environment of the different AGN types are similar except at small scales ($r_p < 100$ kpc), where Type 2 AGNs have more neighbour galaxies than Type 1s. Galaxies located close to Type 2 AGNs ($\sim 100$ kpc) tend to have redder colours, and are more massive compared to the local environment of Type 1s. The observed differences in the environment and host galaxy properties of Type 1 and 2 AGN types show that the obscuration due to the presence of gas and dust may be distributed in larger galactic-scales, possibly originated by galaxy interactions or mergers.

Key words: Galaxies: active – Infrared: galaxies – Galaxies: structure

1 INTRODUCTION

In recent years, the study of Active Galaxy Nuclei (AGN) have become a fundamental part of our understanding of the formation and evolution of galaxies and their systems, such as groups or cluster of galaxies (Miley & De Breuck 2008; Hatch et al. 2014; Dannerbauer et al. 2014; Cooke et al. 2016). It is clear now that most, if not all, galaxies with a bulge/spheroidal component harbor a supermassive black hole at their cores (Kormendy & Bender 2011, and references therein), even low-mass AGNs can harbor supermassive black holes (Filipenko & Ho 2003; Ahn et al. 2017). therefore AGNs influence the formation and evolution of galaxies (Springel et al. 2005a,b; Hopkins et al. 2006). Several related issues such as the relationship between black hole mass and galaxy bulge mass (Magorrian et al. 1998; Marconi & Hunt 2003), or velocity dispersion (Ferrarese & Merritt 2000; Gebhardt et al. 2000; Tremaine et al. 2002; Shen et al. 2008) and the relation between star formation history and the AGN activity through cosmic time (Dickinson et al. 2003; Merloni 2004; Kormendy & Ho 2013) provides further important clues on this topic.

Antonucci (1993) and Urry & Padovani (1995) have proposed a unified scheme for the variety of AGNs. In unified models, distinct spectral signatures between different AGN types would just the result of varying orientation relative to the line of sight. According to their optical spectra, certain AGN types are classified according to the presence of broad emission lines (FWHM $> 2000$ km s$^{-1}$, Broad Line AGNs or Type 1) and narrow emission lines or by the absence of broad permitted emission lines (Narrow Line AGNs or Type 2). In unified models it is expected that a large number of objects present a central torus-shaped obscured region (with sizes of a few parsecs) due to large amounts of gas and dust, that can block broad optical spectral lines produced in the near regions of the accretion disk. If the torus is face on, it is possible detect the broad-line region directly and the galaxies are identified as Type 1 AGN, otherwise, AGN observed through a torus will be classified as Type 2 AGN. A

question that be raised is whether the material that blocks the broad line region is confined to a small central region (few parsecs) in the form of a torus or if the obscuration can be produced by dust distributed at larger galactic scales or (both possibilities at the same time).

In the last years it has been proposed that evolutionary process could produce the obscuration observed in some AGNs. In some models, obscured AGNs represent a phase in the co-evolution of the galaxy an its central black hole. Galaxy formation would be produced by mergers between gas-rich galaxies. In this first phase, the central nuclear region is completely obscured by large amounts of gas and dust. Then, there would be another phase where feedback process would sweep the obscuring material and the system enters in an unobscured, bright optical quasar phase (Hopkins et al. 2006; Springel et al. 2005a).

Within the unified model paradigm, Type 1 and 2 AGNs only differ according to the line of sight with respect to the observer, no differences would be expected in host galaxy properties and they would be expected to have similar local galaxy environment. There are several works on analysis of the environment of AGNs, although the results obtained are contradictory. Jiang et al. (2016) studied the environments of Type 1 and Type 2 AGNs using samples of low-redshift ($z < 0.09$) AGNs, normal galaxies and groups of galaxies selected from the Sloan Digital Sky Survey (SDSS). These authors found that Type 1 and Type 2 AGNs have similar clustering properties on large scales ($\geq 2\text{ Mpc}$), but at scales smaller than 100 kpc, Type 2 have significantly more neighbours than Type 1 AGNs. These results suggest that dark halos hosting Type 1 AGNs, on average, have similar masses to those hosting Type 2, but that Type 1 has less number of surrounding satellites around them. Also, the distribution of Type 2 satellites is more centrally concentrated. These authors also find differences in the host galaxy colours. The optical colour distributions of the host galaxies of the two AGN types are similar, but their infrared colours are significantly different.

Differences between AGN environments are also found at high redshifts. Hickox et al. (2011) studied a sample of mid-infrared obscured and unobscured quasars in the redshift range $0.7 < z < 1.8$, selected from the 9 deg$^2$ Boötes multiwavelength survey. These authors studied the spatial clustering of both AGN types and found a characteristic dark matter halo masses of $\log(M_{\text{halo}}[h^{-1}\text{ M}_{\odot}]) = 12.7$ and 13.3 for unobscured and obscured AGNs, respectively. Similar results were found by Donoso et al. (2014) who calculated the angular correlation function for a sample of $\sim 170,000$ AGNs extracted from the Wide-field Infrared Survey Explorer (WISE) catalog, selected to have a mid-IR colour cut ($W1–W2 > 0.8$). They found that red (obscured) AGNs inhabit denser environments (with a typical dark matter halo mass of $\log(M_h/M_{\odot} h^{-1}) \sim 13.5$) than blue (unobscured) AGNs (with dark matter halo mass of $\log(M_h/M_{\odot} h^{-1}) = 12.8$). In a similar way DiPompeo et al. (2014) calculated the angular clustering of a sample of infrared-selected obscured and unobscured quasars from the WISE survey, but applying a robust and conservative mask to WISE-selected AGNs. These authors found that obscured quasars reside in halos of higher mass: $\log(M_h/M_{\odot} h^{-1}) \sim 13.3$, while unobscured quasar host have $\log(M_h/M_{\odot} h^{-1}) \sim 12.8$.

Geach et al. (2013) present a cross-correlation analysis examining the relationship between the combined Type 1 and 2 quasar population at $z \sim 1$ and the mass that has the cross-power spectrum of the projected mass density as traced by the convergence of the cosmic microwave background lensing field from the South Pole Telescope (SPT). These authors argue that the bias of the combined sample of Type 1 and 2 quasars is similar to that previously determined for Type 1 quasars alone. They conclude that obscured and unobscured quasars trace the mass in a similar way. Gilli et al. (2009) studied the spatial clustering of a variety of high redshift X-ray selected AGNs in the XMM-COSMOS field, adopting different definitions for the source obscuration. They do not find evidence that AGNs with broad optical lines (BLAGN) cluster differently from AGN without broad optical lines (non-BLAGN). Similar results are obtained when considering X-ray absorbed and X-ray unabsorbed AGNs.

In Bornancini et al. (2017) we carried out a similar study to the one presented here, with a sample of mid-infrared selected AGNs, with spectroscopic and/or photometric redshifts, in addition to information in the X-rays. In this paper we presented a more intensive study, with a homogeneous and larger AGN sample obtained by combining X-ray, photometric and optical spectroscopic selections. We also study correlations with other parameters such as stellar masses and non-parametric measurements that allow estimates of host galaxy morphologies. In this paper we extend these studies and investigate the nature of Type 1 and 2 AGNs in order to study their host galaxies, its possible environmental dependence and their relation to unified models.

This paper is organized as follows: In Section 2 we present datasets and samples selection, while in Section 3 we investigate about the properties of Type 1 and 2 AGN host galaxies. The environment of Type 1 and 2 AGNs and their neighbouring galaxies properties is analysed in Section 4. Finally, the summary and conclusions of our work are presented in Section 5. Throughout the work we will use the AB magnitude system (Oke & Gunn 1983) and we will assume the same $\Lambda$CDM cosmology adopted by Laigle et al. (2016) with $H_0 = 70$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.3$, $\Omega_{\Lambda} = 0.7$.

2 DATASETS

Observational data analysed in this paper were obtained from the COSMOS2015 catalog (Laigle et al. 2016) which contains precise photometric redshifts and stellar masses for more than half a million objects over the 2deg$^2$ COSMOS field$^1$ (Scoville et al. 2007). This catalog includes near-UV (0.23 $\mu$m) observations from GALEX (Zamojski et al. 2007), optical observations from the Canada-France Hawaii Telescope (u$^*$-band, CFHT/MegaCam; Sanders et al. 2007), and the COSMOS-20 survey, which is composed of 6 broad bands (B, V, g, r, i, z$^+$)., 12 medium bands (IA427, IA464, IA484, IA505, IA527, IA574, IA624, IA679, IA709, IA738, IA767, and IA827), and two narrow bands (NB711, NB816), taken with Subaru Suprime-Cam (Taniguchi et al. 2007, 2015). Also near-infrared YJHK$*$-band data taken with WIRCam

$^1$ The catalog can be downloaded from ftp://ftp.iap.fr/pub/from_users/hjmcc/COSMOS2015/
Figure 1. Normalised redshift distribution for the final selected Type 1 (solid line histogram) and Type 2 (dashed lines) AGNs. The inset shows the original redshift distribution of the mentioned AGN samples.

and Ultra-VISTA data (McCracken et al. 2010, 2012). This field was also observed in the mid-infrared ([3.6], [4.5], [5.8] and [8.0] μm) from data obtained in the SPLASH-COSMOS survey (Spitzer Large Area Survey with Hyper-Suprime-Cam, PI: P. Capak), S-COSMOS (Sanders et al. 2007), the Spitzer Extended Mission Deep Survey and the Spitzer Can-}

3.1 Mid-infrared colours

It is well-known that AGN are preferentially located in some particular regions of the colour-magnitude diagrams (Hickox et al. 2011, 2007; Bornancini et al. 2017). Hickox et al. (2007, 2011) showed that IR-selected quasars show a bimodal distribution in optical to mid-IR colour (R − [4.5]). These authors use this feature to define two different populations, one consisting of obscured objects in the optical and the other of AGNs with similar properties to Type I QSOs (unobscured). Similar results were obtained by Bornancini et al. (2017) in a sample of obscured and unobscured AGNs by means of a simple optical-MIR colour cut criterion (R − [4.5] = 3.05) with redshifts in the range 1 ≤ z ≤ 2.

In Figure 2 we show the U − [4.5] colour vs. [4.5] microns luminosity (L_{4.5μm}) for the sample of AGNs with 0.3 < z < 1.1 with X-ray emission and selected according to their spectral and photometric features. The luminosity in

2 The catalog can be downloaded from http://irsa.ipac.caltech.edu/data/COSMOS/tables/chandra/
4.5 μm of each AGN, $L_{4.5\mu m}$ was calculated by the following equation,

$$L_\nu (\nu_{\text{rest}}) = \frac{4\pi d_l^2}{1+z} S_\nu (\nu_{\text{obs}}),$$

(1)

where $d_l$ is the luminosity distance for a given redshift, $S_\nu$ is the flux density in ergs cm$^{-2}$ s$^{-1}$ Hz$^{-1}$, and $\nu_{\text{obs}}$ and $\nu_{\text{rest}}$ are the observed and rest-frame frequencies respectively, where $\nu_{\text{rest}} = (1+z)\nu_{\text{obs}}$.

As it can be seen, Type 1 and 2 AGNs present different colour distributions. Type 1 AGN have blue $U-[4.5]$ colours in comparison with the Type 2 sample. Moreover, it is observed a bimodality in the colour distribution of Type 2 objects.

In the last years, several methods have emerged in order to identify AGNs from their colours at IR wavelengths. One of these methods was proposed by Stern et al. (2005) who used mid-infrared observations with the Infrared Array Camera (IRAC) mounted on the Spitzer Space Telescope. In Figure 3 we show the $[3.6]-[4.5]$ versus $[5.8]-[8.0]$ colour-colour magnitude diagram for sources brighter than 3σ detection limits$^3$ in all IRAC four bands ($[3.6] = 25.5$, $[4.5] = 25.5$, $[5.8] = 23.0$ and $[8.0] = 22.50$, Sanders et al. 2007). We also plot the corresponding colours of Type 1 (black filled circles) and 2 (open circles) AGNs. As it can be seen, the colour distribution are significantly different.

Type 1 AGNs are preferentially located within the Stern et al. wedge (dashed lines), although a large fraction of Type 2 objects are located outside the AGN selection boundaries. For Type 1 AGNs we find that 86% of the total sample are located inside the Stern et al. wedge. On the other hand, we find that only 28% of Type 2 AGNs are located within this limits. We also plot in this figure the colour distribution of each AGN type. In the right panel, we show the $[3.6]-[4.5]$ colour distribution of Type 1 (solid line histogram) and Type 2 (in dashed lines). In the case of Type 2 objects, we find a bimodality in the colour distribution, in a similar way of that found in the $U-[4.5]$ colour (see Figure 2), but mid-IR colours appear inverted, i.e. Type 1 AGNs are bluer comparing to the Type 2 sample. In the lower panel of Figure 3 we plot the $[5.8]-[8.0]$ colour distribution. As it can be seen both distributions are similar, except that Type 2 AGN colours are, on average, redder than those of Type 1 AGNs.

In order to quantify the presence of a colour bimodality, we perform a Gaussian mixture modeling (GMM) test. We have used the GMM code of Muratov & Gnedin (2010) to quantify the probability that the colour distributions are better described by a bimodal rather than a unimodal distribution. This code uses information from three different statistic tools: the kurtosis, the distance from the mean peaks ($D$), and the likelihood ratio test (LRT). The kurtosis test measures the degree of peakedness of a distribution: a positive value corresponds to a sharply peaked distribution whereas a negative kurtosis corresponds to a flattened distribution. The distance from the mean peaks or “Bandwidth test”, is the separation between the means of the Gaussian

---

3σ depth in $m_{AB}$ computed from the RMS maps, after masking the area containing an objects based on the segmentation map.
components relative to their widths, calculated as

\[
D = \sqrt{\frac{(\mu_1 - \mu_2)^2}{\sigma_1^2 + \sigma_2^2}},
\]

where \(\mu_1\) and \(\mu_2\) are the mean values of the two peaks of the proposed bimodal distribution, and \(\sigma_1\), \(\sigma_2\) are the corresponding standard deviations. For a clear separation between the two peaks it is required that \(D > 2\).

LRT is defined as

\[
\text{LRT} = 2 \times \left[ \ln(L_{\text{bimodal}}) - \ln(L_{\text{unimodal}}) \right],
\]

where \(L_{\text{bimodal}}\) and \(L_{\text{unimodal}}\) are the likelihood for a bimodal and unimodal distributions, respectively.

The GMM code provides the probability \(p(\chi^2)\) of rejection of a unimodal distribution in favour of a bimodal fit using initial values for the two estimated peaks in the observed distribution. In order to reach a maximum value of \(p(\chi^2)\) we have performed tests with different values of \(\mu_1\) and \(\mu_2\).

For the \(U - [4.5]\) colour distribution of Type 2 AGNs shown in the right panel of Figure 2 (shaded line histogram), we find \(\mu_1 = 3.5 \pm 0.4\) and \(\mu_2 = 5.3 \pm 0.7\), with \(p(\chi^2) = 0.05\), \(D = 2.1 \pm 0.5\), kurtosis = −0.39. The value of \(p(\chi^2)\) indicates that there is 5% probability of the colour data being drawn from a single Gaussian model, rather than the best-fit double Gaussian model.

For the \([3.6] - [4.5]\) colour distribution of Type 2 AGNs shown in the right panel of Figure 3, we find \(\mu_1 = -0.08 \pm 0.05\) and \(\mu_2 = -0.34 \pm 0.04\), with \(p(\chi^2) = 0.004\), \(D = 1.9 \pm 0.2\), kurtosis = 0.97. We notice however, that although \(p(\chi^2)\) is very close to 0, indicating bimodality, the kurtosis is positive. This analysis shows that the colour distribution of Type 2 AGNs is bimodal, and that these objects actually represent two different populations, one consistent with a blue host galaxy population and other consistent with a red host galaxy population.

3.2 Star-forming and quiescent galaxies

The colours of galaxies in the near-UV (NUV), optical \((r-band)\) and near-infrared \((J-band)\) can be used to separate star-forming from quiescent galaxies. Williams et al. (2009) investigated the properties of galaxies with \(K < 22.4\) (AB) and \(z_{\text{phot}} \lesssim 2.5\) selected from the UKIDSS Ultra-Deep Survey, Subaru-XMM Deep Survey and Spitzer Wide-Area Infrared Extragalactic Survey. These authors found two distinct population of galaxies in the rest-frame \(U - V\) vs. \(V - J\) colour space: a clump of red, quiescent galaxies and a track of star-forming galaxies. From an angular cross-correlation analysis, Williams et al. (2009) found that quiescent galaxies are clustered more strongly than those actively forming stars, indicating that galaxies with early-quenched star formation may occupy more massive host dark matter halos. Quiescent galaxies are possibly the progenitors of the most massive, early-type galaxies found locally, although evolutionary mechanisms are poorly understood.

Ilbert et al. (2010) used a slightly modified version of the colour-colour selection technique proposed by Williams et al. (2009). They used the colour NUV − r instead of \(U - V\) since this colour is a better indicator of the star formation activity.

In Figure 4 we plot the rest-frame colour-colour NUV − r vs. \(r - J\) for the AGN sample analysed in this work. Quiescent objects are those with \(M_{\text{NUV}} - M_r > 3(M_r - M_J) + 1\) and \(M_{\text{NUV}} - M_r > 3.1\) (dashed lines) while star-forming galaxies occupy regions outside of this criterion (Ilbert et al. 2010, 2013). As noted by Ilbert et al. (2013) this technique avoids mixing the red dusty galaxies and quiescent galaxies. We find that Type 1 objects are located in the region populated by star-forming galaxies, whereas Type 2 AGNs are divided between the region occupied by quiescent (29%) and star-forming galaxies (71%).

3.3 X-ray properties

In this section we explore the X-ray properties of Type 1 and 2 AGNs, relevant at understanding the population of obscured AGNs which harbor supermassive black holes actively accreting matter. Figure 5 shows the hardness ratio (HR) as a function of hard X-ray luminosity \((2 - 10 \text{ keV})\) for the sample of Type 1 and 2 objects selected in this paper. The hardness ratio (which is an indication of the X-ray spectral shape) is defined as follows:

\[
\text{HR} = \frac{H - S}{H + S},
\]

where \(H\) and \(S\) are the count rates in the hard \((2 - 10 \text{ keV})\) and soft \((0.5 - 2 \text{ keV})\) bands, respectively.

The dashed horizontal line shows the HR value \((\text{HR} = -0.2)\) for a source with a neutral hydrogen column density, \(N_H > 10^{21.6} \text{ cm}^{-2}\) at \(z > 1\) (Gilli et al. 2009), which is used by several authors (Gilli et al. 2009; Treister et al. 2009; Marchesi et al. 2016) to separate obscured and unobscured sources in the X-rays. This is due to the the fact

\[\text{Figure 4. Rest-frame } M_{\text{NUV}} - M_r \text{ vs. } M_r - M_J \text{ colours of Type 1 (filled circles) and Type 2 (open circles) AGNs. Dashed lines show the limits used to empirically separate quiescent from star-forming galaxies from Ilbert et al. (2013).}\]
that soft X-ray emission of obscured AGNs tend to be absorbed, while hard X-ray are able to escape. As it can be seen, sources with hard X-ray spectra (positive hardness ratio) tend to be also classified as Type 2 sources in the optical, while Type 1 AGNs have in general a soft X-ray spectrum (negative hardness ratio). We find that most of the AGNs have X-ray luminosities similar to those found in Seyfert-like galaxies (with $10^{42} \leq L_X < 10^{44}$ erg s$^{-1}$), while only a minority have X-ray luminosities as the observed in QSOs ($L_X > 10^{44}$ erg s$^{-1}$). It can also be seen that there are no objects with $L_X < 10^{42}$ erg s$^{-1}$, which are usually identified with normal galaxies, in agreement with the AGN selection criteria proposed in Section 2.1.

3.4 Morphological analysis

In this section, we will analyse the morphology of the AGN sample identify in this work in order to study differences or similarities between both AGN types. We have used the Cassata's morphological catalog (Cassata et al. 2007) which provides information of five non-parametric diagnostics of galaxy structure, i.e., asymmetry A, concentration C, Gini coefficient G, second-order moment of the brightest 20% of galaxy pixels M20 (e.g., Conselice 2003; Abraham et al. 2003; Lotz et al. 2004), for 232022 galaxies up to F814W=25, using the Advanced Camera for Surveys (ACS) on board Hubble Space Telescope.

The Gini coefficient is defined as the absolute value of the difference between the integrated cumulative distribution of galaxy intensities and a uniform intensity distribution (Abraham et al. 2003) and is a concentration parameter strongly correlated with concentration and surface brightness. However, unlike C, G is independent of the large-scale spatial distribution of the galaxy’s light, i.e that it does not require the galaxy to be circularly symmetric (Abraham et al. 2003). The asymmetry parameter A quantifies the degree to which the light of a galaxy is rotationally symmetric. A is measured by subtracting the galaxy image rotated by 180 degrees from the original image. M20 describes the second-order moment of the brightest 20% of the galaxy’s flux, defined as the sum of the intensity of each pixel multiplied by the square of the distance from the center of the galaxy for the brightest 20% of the pixels in a galaxy. This concentration parameter is sensitive to off-axis clumps and so provides information of merger signatures such as multiple nuclei, tidal tails, bars, etc.

We cross-correlated the spatial positions of objects detected in the Laigle et al. catalog with those presented by Cassata et al., using a matching radius of 1 arcsec. From a total of 152 Type 2 AGNs, we find 138 (90%) matches. Whereas in the case of Type 1 AGNs, we find 100% matches. In Figure 6, left panel, we plot Gini vs. Asymmetry for the sample of Type 1 (filled circles) and Type 2 (open circles) AGNs. We have also include dividing lines between regions of predominantly irregulars, spirals and elliptical morphological types taken from (Capak et al. 2007). The dashed line between irregular and spiral galaxies is defined as $\log_{10}(\text{Asymmetry})=2.353+\log_{10}(\text{Gini})+0.353$, while the solid line between spiral and early-type galaxies is defined as $\log_{10}(\text{Asymmetry})=5.500+\log_{10}(\text{Gini})+0.825$. In Figure 6, right panel, we show the M20 vs. Gini parameters. We have also include dividing lines between regions of mergers, Sb/Sc/Irr and E/S0/Sa galaxy types taken from Lotz et al. (2008), according to the following definitions, Mergers: $G > -0.14+M20+0.33$, Early(E/S0/Sa): $G < -0.14+M20+0.33$, and $G > 0.14+M20+0.80$. Late(Sb/Sc/Irr): $G < -0.14+M20+0.33$, and $G > 0.14+M20+0.80$. We note in Figure 6, left panel, that Type 1 AGN reside in the locus formed by elliptical galaxies or compact objects (Capak et al. 2007). While Type 2 AGNs present a more dispersed distribution. We find that 3.6% of Type 1 AGN are located in the region occupied by irregular galaxies, 18.8% are identified with spiral galaxies and 77.6% with elliptical galaxies. While the majority (80%) of Type 1 objects are located in the region occupied by elliptical or compact objects. Only 2% are located in the region of spiral galaxies. In Figure 6, right panel, we find that 7.7% of Type 1 AGNs are located in the region identified by mergers. This result is in agreement with those found by Chang et al. (2017), who studied a sample of 0.5 < $z$ < 1.5 AGNs selected by their mid-IR power-law emission. These authors do not find a high merger rate in an obscured AGN sample. We also find that 37% of the total Type 1 sample are identified with spiral galaxies of Sb/Sc/Irr types, and 55.3% occupy the region identified with elliptical galaxies. We notice however that the majority of the Type I AGNs are close to the merger region compared to the distribution of Type II AGNs.

3.5 Corrected Colours and Masses

It is known that the presence of an AGN can introduce biases in the measurements of some host galaxy parameters, such as colours, masses, etc. In our case, Laigle et al. (2016) provide colours, stellar masses and star formation rates un-
corrected by the presence of nuclear AGN light contamination. Nevertheless, Pierce et al. (2010) analysed the effect of AGN light in a sample of X-ray-selected AGN host galaxies at $z \sim 1$ finding that integrated optical and UV-optical colours are not significantly affected except in extreme cases (<10%) where the AGN is very luminous, unobscured, and/or visible as a point source. Also, Hickox et al. (2009) analyse different host galaxy properties of AGNs selected by its emission in radio, X-rays and IR wavebands. They calculated the correction for AGN contamination in the $u-r$ host galaxy colours finding that the typical correction for nuclear contamination ranges from 0 to 0.3 mag. Similar results were found by Kauffmann et al. (2007) for a sample of low redshift spectroscopically selected AGNs. These authors compared UV ($NUV-R$) and optical ($g-r$) colours from the central regions to integrated or total colours. They found that the colours are not strongly affected by light from an AGN, i.e. that light from stars in the outer regions of these AGN host galaxies dominates the observed UV-optical colours.

We also carried out a visual inspection of high resolution (0.03’’/pixel) HST images (F814W filter) of our sample of AGNs finding that only 12% of type I AGNs present visible nuclear point source in their optical images. Following the previous results, we estimate that the correction for AGN contamination on host galaxy colours is less than $\sim$0.3 mag. and so the results are not affected.

Despite this, in this and the following subsections we will used U-B colours and stellar masses corrected for AGN light contamination. For this reason, we cross-correlated our AGN samples with the catalog presented in Bongiorno et al. (2012). These authors calculated colours, stellar masses and star-formation rates (SFR) of a sample of X-ray AGNs selected from the XMM-COSMOS catalog. These parameters...
were calculated on a careful study of their spectral energy distributions, which have been parametrized using a two-component (AGN+galaxy) model fit. From our total AGN sample, we find that 101 (70%) and 50 (87%) Type 2 and 1 AGNs are in the catalog presented by Bongiorno et al. (2012).

As mentioned by Bongiorno et al. (2012), there is a problem with SFR determinations for Type 1 AGNs. These authors find that the accretion disc of Type 1 AGNs contributes significantly to the emission in the UV bands, which causes a degeneration in the SED fitting method of unobscured objects when considering between the UV emission from the star-formation of the host galaxy and that produced by the central AGN. For this reason we have not performed any analysis with this parameter for the case of AGNs.

Host galaxy colours are important for revealing the nature of AGN host galaxies. It is well-known that the distribution of optical colours in normal galaxies is bimodal, where the predominantly red early-type galaxies occupy a distinct locus in colour from the blue star-forming galaxies (Baldry et al. 2004; Salim et al. 2007). It can also be seen an intermediate region called the “green valley”, the region proposed to be the transitional phase in galaxy evolution where galaxies are moving from later-to-earlier-types (Martin et al. 2005, 2007).

In Figure 7 we plot the rest-frame $U − B$ vs. $M_B$ corrected colours of Type 1 and Type 2 AGNs (left panel). We have also included the criteria to separate the colours of the “green valley” galaxies ($0.8 ≤ U − B ≤ 1.2$; Nandra et al. 2007; Willmer et al. 2006; Mahoro et al. 2017). In the right panel we show the colour distribution of the different AGN types. For Type 2 AGNs, we find that 40.5% are located in the red sequence of bulge-dominated, passively evolving galaxies, 51.5% are found in the “green valley” between the red sequence and the blue cloud, and only 8% are distributed along the blue cloud (generally disk-dominated, star-forming galaxies). While for the sample of Type 1 AGNs, we find 41.5%, 32% and 26.5% located in the red sequence, the “green valley” and the blue cloud, respectively. As in previous works (Hickox et al. 2009), we find that our AGN sample lie predominantly in the “green valley” of the colour–magnitude diagrams.

3.5.1 Mass vs. redshift

In Figure 8 we plot host galaxy stellar masses (MASS$_{BEST}$) versus photometric redshift for the entire galaxy sample (gray dots). We also include the corresponding values for the AGN sample obtained from Bongiorno et al. catalog; open and filled dots represent Type 2 and 1 AGNs, respectively. In the case of AGNs we plot the spectroscopic redshift values. In the left panel we show the corresponding distribution of stellar mass for Type 1 (solid line histogram) and Type 2 (dashed line histogram). We also included the stellar mass distribution for galaxies in the same range of redshifts as the sample of AGNs (dot-dashed line histogram).

As it can be seen, AGNs reside in the most massive host galaxies at any redshift and both AGN types show similar host galaxy stellar mass distributions. For the Type 1 sample we find a mean value $\mu_1 = 10.6$ and a standard deviation $\sigma_1 = 0.5$. For the Type 2 sample we find $\mu_2 = 10.8$ and $\sigma_2 = 0.3$. For galaxies in the same range of redshifts as the sample of AGNs, we find $\mu_g = 8.8$ and a standard deviation $\sigma_g = 1.$

4 TYPE 1 AND 2 AGN ENVIRONMENTS

4.1 Galaxy density

It is well-known that galaxy environment has a fundamental effect on the properties of galaxies and their evolution (Darvish et al. 2015; Muldrew et al. 2012). ZZ If the postulates of the unified model are true, then it would be expected that the galaxy environments of the different AGN types would be similar. In this Section we analyze the environment of Type 1 and 2 AGNs.

In Figure 9 we show the projected radial density of tracer galaxies with $|z_{AGN} − z_{galaxy}| ≤ 0.2$ and $r < 26.5$ (which is the 3$\sigma$ detection limits in the Subaru $r$ band images, Laigle et al. 2016) around the obscured and unobscured AGNs with $r_g < 500$ kpc. Error bars were estimated using Poissonian errors. The radial distribution of tracer galaxies in both AGN samples are similar, except that in small scales Type 2 AGNs have more neighbouring galaxies than the sample of Type 1 AGNs.

We have also performed tests using other redshift limits, changing the redshift difference cut to $|z_{AGN} − z_{galaxy}| ≤ 0.1$ and 0.15 does not change the results except that the number of tracer galaxies is reduced.
Environment and properties of high redshift AGNs

4.2 Neighbour galaxy properties

Several studies have shown that galaxy environment correlate with galaxy properties such as morphology (Dressler 1980; Postman & Geller 1984; Alpaslan et al. 2015), colour (Tanaka et al. 2004; Balogh et al. 2004), and SFR (Grützbauch et al. 2011).

Here we study colour, masses, and SFR of neighbour tracer galaxies located in the field of Type 1 and 2 AGN samples. In Figure 10 we show the $NUV - r$ colour (left panel), stellar masses (M$\text{ASS}_{\text{BEST}}$, middle panel), and SFR (left panel) for tracer galaxies with $|z_{\text{AGN}} - z_{\text{galaxy}}| \leq 0.2$ and $r < 26.5$ within 500 kpc from Type 1 and Type 2 AGNs. As it can be seen, the colours of tracer galaxies at $r_p < 500$ kpc show no difference between both AGN samples. We have included the cumulative fraction distribution for these samples (top right on each figure), in order to make clearer the differences between the different distributions. Following the results shown in Figure 9, we have studied the distribution of the same parameters on smaller scales $r_p < 100$ kpc. Contrary to what was found at larger projected radius, differences in the colour and mass distribution of tracer galaxies (see Figure 11) are clear. Small-scale environments around AGN reveals that neighbour galaxies in the field of Type 2 AGNs tend to have red $NUV - r$ colours compared with the galaxy environment of Type 1 AGNs. This result implies that at larger scales the colour of tracer galaxies around the sample of AGNs are similar, and the differences are only significant at small scales, $r_p < 100$ kpc, around both AGN samples. In Figure 10, right panel, we can see that there is no difference between the SFR distribution of tracer galaxies in both AGN samples at larger scales ($r_p < 500$ kpc).

5 SUMMARY AND DISCUSSION

In this paper we study the host galaxies properties and environment of a well designed sample of Type 1 and 2 AGNs at high redshifts ($0.3 < z < 1.1$) from the COSMOS2015 survey identified on the basis of their spectral, photometric and X-ray emission properties.

The main results are:

- Type 1 and 2 AGNs exhibit different colour distribution in the mid-IR and in the optical to mid-IR. Type 1 AGN have blue $U - [4.5]$ colours in comparison with the Type 2 sample. We observed that the optical to mid-IR colour distribution of Type 2 objects present a bimodality, indicating two different host galaxies populations. While the $[3.6] - [4.5]$ colour distribution appear inverted, i.e. Type 1 AGNs are bluer comparing to the Type 2 sample.
- From the rest-frame $M_{\text{NUV}} - M_{\text{B}}$ vs. $M_{\text{B}} - M_{\text{J}}$ plane, we find that different AGNs are located in two particular regions: Type 1 are identified in the regions occupied by star-forming galaxies, whereas 29% of Type 2s are identified in the locus occupied by quiescent galaxies, while the rest belong to the region populated by star-forming galaxies.
- According to the analysis carried out in the X-rays, we find that most of the AGNs have X-ray luminosities similar to those found in Seyfert-like galaxies (with $10^{42} \lesssim L_X < 10^{44}$ erg s$^{-1}$), while only a minority have X-ray luminosities as the observed in QSOs ($L_X > 10^{44}$ erg s$^{-1}$). The Hardness ratio values of Type 1 AGNs are also in agreement with the expected values for unobscured X-ray sources.
- Morphological analysis according to non-parametric measurements (Gini vs. Asymmetry) shows that the majority of Type 1 AGNs are located in the region occupied by elliptical or compact galaxies. While Type 2 AGNs present more scatter, from those occupied by spiral, irregulars and elliptical galaxies. From the Gini vs. M20 plane, we find that only a small fraction (3.8%) of the total sample of AGNs are located in the region of mergers. While the rest is located almost equally distributed between the region occupied by early types (E/S0/Sa) and late types (Sb/Sc/Irr). Recently, Chang et al. (2017) presented an analysis of IR-selected AGNs in the COSMOS survey. They found also that only half of the most powerful AGNs present evidence of galaxy major mergers. These authors postulate that AGN activity might be triggered by internal mechanisms, such as secular processes, disk instabilities, and compaction in a particular evolutionary stage.
- No significant difference is found between the Type 1 and Type 2 AGN host stellar masses, which on average show the same host galaxy mass distribution. We find that both AGN types represent the most massive galaxies at any redshift.
- The environment of the different AGN types are similar. The only difference is found at small scales ($r_p < 100$ kpc) around the Type 2 sample. Type 2 sources have more neighboring galaxies than Type 1.
- The environment of the different AGN types are similar. The only difference is found at small scales ($r_p < 100$ kpc) around the Type 2 sample. Type 2 sources have more neighboring galaxies than Type 1.
- We study colour, masses, and star-formation rates (SFR) of neighbour tracer galaxies located in the field of Type 1 and 2 AGN samples. Neighbouring galaxies located within 100 kpc and with $|z_{\text{AGN}} - z_{\text{galaxy}}| \leq 0.2$ from Type 2 AGNs are redder and more massive than the neighbouring galaxies in the field of Type 1 sources. We do not find any...
differences in the SFR distribution of tracer galaxies in both AGN samples.

These results suggest that the host galaxies of Type 1 and 2 AGNs present different optical, mid-IR, X-ray and morphological properties and also different galaxy environments. These last results are in agreement with those found by Jiang et al. (2016), previously commented at low redshifts and Koulouridis et al. (2006), who found that the fraction of Seyfert 2 galaxies with a close neighbour (within a projected distance of 100 kpc) is significantly higher than that of their control and Seyfert 1 galaxy samples. Similar results were found by Dultzin-Hacyan et al. (1999) who observed a significant excess of large companions galaxies within a radius of 100 kpc. Other studies also find differences in the environment of distinct AGNs at high redshifts. Although the selection criteria vary from one job to another, several works found that Type 2 (obscured) and Type 1 (unobscured) AGNs reside in different galaxy environments. These differences are also observed in the auto cross-correlation function calculated for a sample of obscured and unobscured AGNs selected from mid-IR colour cuts at high redshift (Hickox et al. 2011; Donoso et al. 2014; DiPompeo et al. 2014).

We think that the AGN obscuration observed in Type 2s is possibly due to galaxy interactions or mergers. Although the results found in the morphological analysis show that only a small fraction of the AGNs are mergers, we consider the possibility that after galaxy mergers, there are still large amounts of dust that obscure the central engine. This proposal is in agreement with the results obtained by Goulding et al. (2012), who concluded that the dust located in the host galaxy, in a sample of local Compton-thick AGNs, is responsible for the dominant contribution to the observed mid-IR dust extinction and not necessarily a compact obscuring torus surrounding the central engine.

We find different AGN host galaxy properties, environments and neighboring galaxies in a sample of Type 1 and 2 AGNs. These results are more related to evolutionary sequences than to the Unified model schemes. The obscuration due to the presence of gas and dust can be distributed in larger galactic-scales and can be due possibly to an evolutionary process produced by galaxy interactions or mergers.

ACKNOWLEDGMENTS

We are grateful to the anonymous Referee for his/her careful reading of the manuscript and a number of comments, which improved the the quality of this manuscript. Based on data
