(Received 22 June 2012; published 13 August 2012)

Neutron diffraction measurements on a high quality single crystal of CeAu$_2$Ge$_2$ reveal two magnetic structures that coexist with commensurate long-range antiferromagnetic order below the Néel temperature $T_N \approx 14$ K. The magnetic structures, which exhibit distinct temperature and field dependencies, are described by both commensurate and incommensurate magnetic structures and introduce a new region in the $H-T$ phase diagram. These experimental observations provide important information for developing a universal understanding of the magnetic properties of this class of Ce-based Ce$X_2M_2$ ($X = $ Cu, Ag, Au; $M = $ Ge, Si) compounds, which are prototypes for exploring quantum phase transitions, and their interplay with unconventional superconductivity.

DOI: 10.1103/PhysRevB.86.060405  PACS number(s): 75.25.-j, 74.40.Kb, 75.30.Fv, 75.30.Kz

The study of Ce-based intermetallic compounds has proved to be a fertile testing ground for many important phenomena in strongly correlated electron systems, such as magnetic quantum critical phenomenon and its interplay with superconductivity, and non-Fermi-liquid behavior. $^{1,2}$ In recent years, a significant amount of research in this field has focused on understanding the underlying mechanism behind quantum phase transitions $^{3-11}$—as found in many Ce$X_2M_2$ compounds, where $X$ is a transition metal element and $T$ is Si or Ge—and develop a universal formulation which will have a strong impact in understanding the physics of unconventional magnetic superconductors. $^{3-5}$ Ce$X_2M_2$ crystallizes in the ThCr$_2$Si$_2$-type tetragonal structure ($I4/mmm$ space group), where the Ce valence spans the range from a fully trivalent to a strongly mixed valent as $X$ and $T$ are varied. $^{9,10}$ Depending on the strength of the Ce ion $f$-band electron hybridization with the delocalized bands, the ground state properties can vary from the Kondo-interaction-dominated single-ion phenomenon to the Ruderman-Kittel-Kasuya-Yoshida (RKKY) interaction mediated long-range magnetic ordered state. $^{12}$ The RKKY interaction acts as the mediating agent between the hybridized quasiparticles which often lead to the spin-density-wave instability of the local moments of $f$ electrons in the Fermi liquid of itinerant electrons.

In Ce$X_2M_2$ compounds where $M = $ Ge, neutron scattering measurements have revealed a spin-density-wave type ground state magnetic configuration for $X = $ Cu and Ag. $^{13,15}$ Since CeAu$_2$Ge$_2$, which is the weakest heavy fermion metal of the Ce$X_2Ge_2$ series, $^{13}$ belongs to the same noble metal group of elements ($X = $ Cu, Ag, Au), a natural corollary is expected but has never been observed. The magnetic susceptibility of CeAu$_2$Ge$_2$ exhibits strong anisotropy with an easy [001] direction perpendicular to the tetragonal plane. $^{16,17}$ Previous measurements on a powder of CeAu$_2$Ge$_2$ showed that the correlated Ce ions develop a long-range antiferromagnetic order below $T_N \approx 16$ K. $^{13}$ In this Rapid Communication, we report elastic neutron scattering measurements on a high quality single-crystal sample of CeAu$_2$Ge$_2$. The crystals were synthesized by a high temperature solution growth method using Bi flux and the quality was verified using x-ray measurements. $^{16}$ Our neutron scattering measurements reveal magnetic structures, in addition to the long-range magnetic order found in previous powder measurements, that evolve as a function of temperature and are strongly field dependent. The main result of this Rapid Communication is the observation of incommensurate magnetic vectors $q$ with the temperature-dependent propagation wave vector $\epsilon = (0.055,0.055,0.055)$ at 4.5 K in reciprocal lattice units of $2\pi/a$, $2\pi/b$, and $2\pi/c$, respectively, with $a = b = 4.39$ Å and $c = 10.46$ Å at 10 K in the tetragonal unit cell. The incommensurate magnetic peaks appear in a narrow temperature range of 2.5 K $\leq T \leq$ 8.5 K. Interestingly, the incommensurate wave vector emerges in all three reciprocal directions. An additional magnetic phase is also found to exist with the propagation wave vector $\epsilon_L = (0,0.0.25)$ along the crystallographic direction $L$, which exhibits a different temperature dependence compared to both the commensurate antiferromagnetic order and the incommensurate order.

Neutron scattering measurements were performed on a 0.7 g single-crystal sample of CeAu$_2$Ge$_2$ at the SPINS cold triple-axis spectrometer with a fixed final neutron energy of 3.7 meV. The measurements employed a flat pyrolytic graphite (PG) analyzer with a collimator sequence mono-80′-flat analyzer-120′. For higher wave vector resolution measurements at a fixed final neutron energy of 5 meV, the collimator sequence was mono-40′-sample-BeO-80′-flat analyzer-120′. Measurements were performed with the crystal oriented in both the ($H K 0$) and ($H 0 L$) scattering planes. For the measurements in magnetic field, the crystal was oriented in the ($H K 0$) plane and mounted in a cryomagnet with a base temperature of $\approx$2 K. The field was applied along the easy [001] direction.

Previous measurements on powder CeAu$_2$Ge$_2$ (Ref. 13) identified magnetic reflections with commensurate long-range antiferromagnetic order. $^{13}$ The present single-crystal measurements allow for a much more detailed examination of the intensities and magnetic scattering pattern, which reveal qualitatively different features. In Fig. 1(b), we plot elastic representative scans at different temperatures across the [102] magnetic Bragg peak. As the sample is cooled below 14 K, resolution-limited magnetic peaks clearly appear indicating the development of commensurate long-range magnetic order.
in the system. A plot of peak intensity versus temperature at the magnetic peak position [102] is shown in Fig. 1(c). The low temperature elastic measurements show Bragg peaks at the positions \( h + k + l = 2n + 1 \) [shown in Fig. 1(a)], which are systematically absent in the crystal structure. This shows that the ground state magnetic configuration is antiferromagnetic in nature. The magnetic moment of the ordered Ce ion at 3.5 K is determined to be 1.61(3)\( \mu_B \) with the moment along the \( c \) axis.

The observation of long-range antiferromagnetic order at low temperature in CeAu2Ge2 is consistent with the previous measurements. However, as the sample is cooled below 10 K, different magnetic peaks start appearing with different temperature dependencies. As shown in the series of plots in Figs. 1(d)–1(l), two additional sets of magnetic peaks manifesting different magnetic components appear at \( T \leq 10 \) K. In one case, incommensurate magnetic peaks with a width broader than the instrument resolution develop across the long-range magnetic order peaks, for example, [100], below 9 K. Most remarkably, the incommensurate peaks appear in all three crystallographic directions of [H00], [0K0], and [00L]. The modulation vector \( \epsilon \) describes the incommensurate peak positions \( \mathbf{q} \) defined by \( \mathbf{q} = \mathbf{\tau} \pm \epsilon \), where \( \mathbf{\tau} \) and \( \epsilon \) are the antiferromagnetic and modulation vectors, respectively. \( \epsilon \) is found to be temperature dependent with \( \epsilon = (0.055, 0.055, 0.055) \) reciprocal-lattice units (r.l.u.) at \( T = 4.5 \) K. With a further decrease in temperature \( T < 2.5 \) K, the incommensurate peaks disappear. We performed detailed temperature dependence measurements of the incommensurate magnetic behavior at \( \mathbf{q} = (0, 0.945, 0) \) using the higher resolution collimator sequence. Representative scans at a few different temperatures at 2.5 K \( \leq T \leq 9 \) K are plotted in Fig. 2(a).

A Gaussian line shape is found to be the best fit to the experimental data. As the measurement temperature decreases, the position of the incommensurate peak clearly shifts away from the long-range order peak position at [010] [Fig. 2(b)]. In Figs. 2(c) and 2(d), we have plotted the temperature dependencies of the integrated intensity and full width at half maximum (FWHM). The spectrometer resolution has been removed from the fitted values of FWHM. As we can see...
in Fig. 2(c), the integrated intensity of the incommensurate peak gradually rises below 9 K, and attains a maximum at 3.5 K before suddenly disappearing below 2.5 K. At the same time, we find that the width of the peak, which is slightly broader than the instrumental resolution at $T \approx 8$ K, becomes resolution limited at low temperature. We did not observe any lock-in transition or higher harmonics of the incommensurate wave vectors at $T = 2.5$ K. We also note that the intensities of the incommensurate peaks are quite small, $\approx 1/30$ times compared to the intensity of the long-range order peaks. Because of the geometrical constraints at the spectrometer location, our measurements were limited to two antiferromagnetic positions $[100]$ and $[102]$ only. Therefore it was not possible to determine the detailed nature of the magnetic configuration or the ordered moment of Ce ions associated with the incommensurate magnetic structure.

In addition to the long-range antiferromagnetic order and the incommensurate magnetic structure, a third type of magnetic structure develops along the $[00\ell]$ crystallographic direction. In this case, the resolution-limited magnetic peaks appear below $T \approx 10$ K and are described by the propagation vector $\epsilon_L = (0.0, \pm 0.25)$ r.l.u., as shown in Figs. 1(j)–1(l). The magnetic peaks grow stronger as the temperature is reduced. A different temperature dependence of these magnetic peaks compared to both the long-range ordered antiferromagnetic (AFM) peaks and the incommensurate magnetic peaks suggests another magnetic component of correlated Ce ions in CeAu$_2$Ge$_2$. Since the third magnetic structure is represented by the commensurate magnetic peaks along the $[00\ell]$ direction only, the magnetic configuration for this component of the Ce moments can be described by an arrangement where the Ce spins are lying in the crystallographic plane of $[HK0]$ and antiferromagnetically aligned with the nearest neighbors, with the magnetic unit cell extended by four times of the underlying lattice unit cell along the $[00\ell]$ direction. All three magnetic components exhibit different temperature dependencies and different types of magnetic correlations.

Previous field-dependent work suggests that CeAu$_2$Ge$_2$ undergoes a metamagnetic transition at $H \approx 4.5$ T. At sufficiently low temperatures, the nature of magnetic correlations of Ce ions changes from long-range antiferromagnet to field-induced ferromagnet at $H \geq 4.5$ T. In Fig. 3, we have plotted elastic scans at various fields along $c$ at two temperatures, 1.9 and 4.5 K. As we can see, the peak intensity of the $[100]$ peak, associated with the commensurate antiferromagnetic order, gradually diminishes and eventually disappears at $H \approx 5.1$ T at $T = 1.9$ K. The field measurements at $T = 4.5$ K reveal that the incommensurate peaks exhibit a different field dependence compared to the primary long-range antiferromagnetic phase. In fact, the incommensurate peaks suddenly disappear at $H \approx 3.5$ T, indicating a first-order magnetic transition. The field dependence of this phase is described in Fig. 4(a), where the distinct field dependence providing additional evidence of multiple magnetic structures in CeAu$_2$Ge$_2$.

In Fig. 4(b) we have summarized our observations using an $H$-$T$ phase diagram for elastic measurements in the $[HK0]$ crystallographic plane. The additional magnetic structures that develop below the primary ordering temperature have different temperature and field dependencies than the quadrupolar order observed in PrPb$_3$ and therefore appear to have a different origin. A quadrupolar order generally results from the degenerate orbital level which carries a quadrupolar moment. These small moments are strongly field dependent and become stronger as the applied field is increased, which is opposite to what we observe. Another possibility is that these additional magnetic peaks arise due to the intermixing of low-lying crystal field levels. Previous as well as recent work on both polycrystalline and single-crystal samples suggest that the crystal field level scheme in CeAu$_2$Ge$_2$ consists of three doublets at $\Delta_0 = 0$ K, $\Delta_1 \approx 12$ meV, and $\Delta_2 \approx 18$ meV. The ground state is almost pure $J_\zeta = \pm 5/2$ with an admixture of $\pm 3/2$. The first excited doublet state is high enough in energy to avoid any significant intermixing between the ground and first excited state doublets, so that any induced moment magnetic state is highly unlikely.

In order to understand the emergence of the magnetic structures in CeAu$_2$Ge$_2$, we need to consider the origin and the type of magnetic order in the whole group of Ce$X_2$Ge$_2$ compounds, where $X = $ Cu, Ag, and Au. In this group, both CeCu$_2$Ge$_2$ and CeAg$_2$Ge$_2$ compounds exhibit incommensurate spin-density-wave type long-range magnetic order. The spin-density-wave type magnetic configuration originates...

FIG. 4. (Color online) (a) Integrated intensity vs field for both LRO and a representative IC peak (inset) at $q = (0.955,0.0)$. (b) $H$-$T$ phase diagram for CeAu$_2$Ge$_2$. In addition to the long-range order (LRO), the incommensurate structure (IC) also exists in a narrow $H$-$T$ region.

from the strong hybridization between conduction bands and the $4f$ band of Ce ions via the Kondo interaction, which also gives rise to the heavy fermion character of the quasiparticles. It is interesting to note that as we move down the group, the heavy fermion character becomes weaker with CeCu$_2$Ge$_2$ as the heaviest. Recent electrical transport measurements on single-crystal CeAu$_2$Ge$_2$ reveal that the magnetoresistance (MR) initially decreases with field followed by an upward turn above $H \simeq 3$ T and then decreases sharply above $H \simeq 4$ T. The authors explained their observation by invoking a weak Kondo interaction in this compound. The MR at $T \simeq 4$ K is more negative than the MR at 2 K. Also, this behavior in MR is observed in a narrow temperature range of 2.5 K $\leq T \leq 8$ K, which is the same temperature range where the weak incommensurate magnetic structure exists in CeAu$_2$Ge$_2$. Therefore, we argue that this incommensurate phase in CeAu$_2$Ge$_2$ possibly results from the weak Kondo coupling between the $4f$ band of Ce ions and the conduction bands. The weak heavy fermion character in this compound was also observed in the previous powder measurements. We would like to mention that the magnetic phases have also been reported in the thermodynamic measurements on single-crystal samples of CeAu$_2$Ge$_2$ in a recent report. Interestingly, the physical and thermodynamic properties were found to be dependent on the flux selection of the sample preparation. Further experimental and theoretical investigations are highly desirable to understand in detail the phase diagram proposed in Fig. 4.

These experimental results possibly suggest the presence of a universal pattern in the magnetic configuration of this class of Ce-based materials. A comprehensive understanding of the magnetic states of Ce$_2$M$_2$ compounds is highly desirable as many members of this class exhibit different quantum critical phenomena and unconventional superconductivity. Future experimental work on the spin dynamics should prove particularly illuminating as soon as single-crystal samples large enough for inelastic studies become available.
