A Membrane-Bound Cytochrome Enables *Methanosarcina acetivorans* To Conserve Energy from Extracellular Electron Transfer

Dawn E. Holmes,a,b Toshiyuki Ueki,a Hai-Yan Tang,a,c Jinjie Zhou,a,d Jessica A. Smith,a,e Gina Chaput,a Derek R. Lovleya

ABSTRACT
Extracellular electron exchange in *Methanosarcina* species and closely related *Archaea* plays an important role in the global carbon cycle and enhances the speed and stability of anaerobic digestion by facilitating efficient syntrophic interactions. Here, we grew *Methanosarcina acetivorans* with methanol provided as the electron donor and the humic analogue, anthraquione-2,6-disulfonate (AQDS), provided as the electron acceptor when methane production was inhibited with bromoethanesulfonate. AQDS was reduced with simultaneous methane production in the absence of bromoethanesulfonate. Transcriptomics revealed that expression of the gene for the transmembrane, multiheme, c-type cytochrome MmcA was higher in AQDS-respiring cells than in cells performing methylotrophic methanogenesis. A strain in which the gene for MmcA was deleted failed to grow via AQDS reduction but grew with the conversion of methanol or acetate to methane, suggesting that MmcA has a specialized role as a conduit for extracellular electron transfer. Enhanced expression of genes for methanol conversion to methyl-coenzyme M and the Rnf complex suggested that methanol is oxidized to carbon dioxide in AQDS-respiring cells through a pathway that is similar to methyl-coenzyme M oxidation in methanogenic cells. However, during AQDS respiration the Rnf complex and reduced methanophenazine probably transfer electrons to MmcA, which functions as the terminal reductase for AQDS reduction. Extracellular electron transfer may enable the survival of methanogens in dynamic environments in which oxidized humic substances and Fe(III) oxides are intermittently available. The availability of tools for genetic manipulation of *M. acetivorans* makes it an excellent model microbe for evaluating c-type cytochrome-dependent extracellular electron transfer in *Archaea*.

IMPORTANCE
The discovery of a methanogen that can conserve energy to support growth solely from the oxidation of organic carbon coupled to the reduction of an extracellular electron acceptor expands the possible environments in which methanogens might thrive. The potential importance of c-type cytochromes for extracellular electron transfer to syntrophic bacterial partners and/or Fe(III) minerals in some *Archaea* was previously proposed, but these studies with *Methanosarcina acetivorans* provide the first genetic evidence for cytochrome-based extracellular electron transfer in *Archaea*. The results suggest parallels with Gram-negative bacteria, such as *Shewanella* and *Geobacter* species, in which multiheme outer-surface c-type cytochromes are an essential component for electrical communication with the extracellular environment. *M. acetivorans* offers an unprecedented opportunity to study mechanisms for energy conservation from the anaerobic oxidation of one-carbon or-

ganic compounds coupled to extracellular electron transfer in Archaea with implications not only for methanogens but possibly also for Archaea that anaerobically oxidize methane.

**KEYWORDS** AQDS reduction, Methanosarcina, c-type cytochrome, extracellular electron transfer, genetics, transcriptome

Extracellular electron exchange is central to the environmental function of diverse Archaea that oxidize and/or produce methane. Some methanogens can divert electrons from methane production to the reduction of extracellular electron carriers such as Fe(III), U(VI), V(IV), and anthraquinone-2,6-disulfonate (AQDS), a humic acid analog (1–9). Diversion of electron flux from methane production to extracellular electron transfer may influence the extent of methane production and metal geochemistry in anaerobic soils and sediments. Methanogens such as Methanothrix (formerly Methanosaeta) and Methanosarcina species can accept electrons via direct interspecies electron transfer from electron-donating partners, such as Geobacter species, in important methanogenic environments such as anaerobic digesters and rice paddy soils (10–12). Anaerobic methane oxidation also plays an important role in the global carbon cycle and diverse anaerobic methane-oxidizing archaea (ANME) transfer electrons derived from methane oxidation to extracellular electron acceptors, such as other microbial species, Fe(III), or extracellular quinones (13–20). The electrical contacts for extracellular electron exchange have yet to be definitively identified in any of these Archaea.

It has been hypothesized that outer-surface cytochromes enable electron transfer to electron-accepting microbial partners or Fe(III) in some ANME (13–19). Genes for multiheme c-type cytochromes that are present in ANME genomes can be highly expressed and in some instances the encoded proteins have been detected (14, 19). The putative function of outer-surface cytochromes is terminal electron transfer to extracellular electron acceptors, similar to the role that outer surface c-type cytochromes play in extracellular electron transfer in Gram-negative bacteria such as Shewanella and Geobacter species (21–23). Similar c-type cytochrome electrical contacts have been proposed for Fe(III)-reducing Archaea, such as Ferroglobus and Geoglobus species (24–26). However, the study of the mechanisms for extracellular electron transfer in these archaea has been stymied by the lack of microorganisms available in pure culture that can grow via extracellular electron transfer and are genetically tractable.

Tools are available for genetic manipulation of the methanogen Methanosarcina acetivorans (27–29). A methyl-coenzyme M reductase from an uncultured ANME was introduced into *M. acetivorans* to generate a strain that could convert methane to acetate with simultaneous reduction of Fe(III) (30). Most of the electrons from the methane consumed were recovered in acetate (30), and it was not shown that energy was conserved from Fe(III) reduction. *In vitro* reactions catalyzed by membrane vesicles of wild-type *M. acetivorans* suggested that the membrane-bound heterodisulfide reductase HdrDE reduced Fe(III)-citrate and AQDS and that an outer-surface multiheme c-type cytochrome might also function as a potential electron donor for Fe(III)-citrate reduction (31). However, *in vitro* assays with cell components are not a definitive approach for determining the physiologically relevant mechanisms involved in the reduction of Fe(III) and AQDS. This is because constituents that do have access to extracellular electron acceptors *in vivo* are exposed to extracellular electron acceptors *in vitro* and many reduced cofactors and redox-proteins, including c-type cytochromes, can nonspecifically reduce these electron acceptors (32). Analysis of the phenotypes of intact cells that result from specific gene deletions can provide more conclusive evidence.

We report here that *M. acetivorans* can be grown without methane production with AQDS as the sole electron acceptor. Analysis of gene expression patterns and pheno-
types of gene deletion strains suggest a mechanism for energy conservation during extracellular electron transfer.

RESULTS AND DISCUSSION

Growth of *M. acetivorans* with AQDS as the sole terminal electron acceptor. In medium with methanol provided as the electron donor and AQDS as a potential electron acceptor, *M. acetivorans* simultaneously produced methane and reduced AQDS (Fig. 1a). The addition of bromoethanesulfonate (BES) inhibited methane production and increased the extent of AQDS reduction (Fig. 1B; Fig. S1). The metabolism of methanol (Fig. 1c) was accompanied by an increase in cell numbers (Fig. 1D). In the BES-amended cultures, 6.3 ± 0.43 mM (mean of triplicate cultures ± the standard deviation) methanol was consumed with the reduction of 15.7 ± 0.61 mM AQDS. When the need to divert some of the methanol metabolized to cell biomass is considered, this stoichiometry is consistent with the oxidation of methanol to carbon dioxide, with AQDS serving as the sole electron acceptor: $\text{CH}_3\text{OH} + 3\text{AQDS} + \text{H}_2\text{O} \rightarrow 3\text{AH}_2\text{QDS} + \text{CO}_2$. Methanol consumption stopped once all the AQDS was reduced in the BES-amended cultures (Fig. 1C). However, in the absence of BES, all of the methanol could be consumed because methanol was also converted to methane.

The growth of *M. acetivorans* with AQDS as the sole electron acceptor (Fig. 1) is the first example of a methanogen conserving energy to support growth with electron transfer to an external electron acceptor. The ability of *M. acetivorans* to grow in this manner and the availability of tools for genetic manipulation (27–29) provide an opportunity for functional analysis of extracellular electron transfer by an archaeon.

Transcriptomics and gene deletion studies demonstrate that the multiheme c-type cytochrome MmcA is involved in AQDS reduction. In order to obtain insight into potential electron carriers involved in AQDS reduction, the transcriptome of cells grown with AQDS as the sole electron acceptor in the presence of BES was compared
to the transcriptome of cells grown with methanol in the absence of AQDS or BES, so that methane production was the sole route of electron flux. The generation time (0.69 ± 0.13 days) of the cells grown via methanogenesis (Fig. S2) was longer than previously reported (generation time, 6.3 h; [33]). The lower growth rate in our study might be due to the omission of cysteine and lower sulfide content in our medium (0.3 mM compared to 0.5 mM) in order to reduce medium constituents that might abiotically reduce AQDS. However, methanogenic growth was ~4-fold faster than growth via AQDS respiration in the presence of BES (generation time, 2.9 ± 0.18 days). Consistent with the lower growth rate, most of the genes related to cell growth (amino acid biosynthesis; protein synthesis; biosynthesis of purines, pyrimidines, nucleosides, and nucleotides; and transcription) had greater expression in methanogenic cells than cells grown via AQDS respiration (see Table S1B in the supplemental material).

Remarkably, despite the lower growth rate on AQDS, the gene MA0658, which encodes a seven-heme, outer-surface c-type cytochrome, was 4.5-fold more highly expressed in AQDS-reducing versus methanogenic cells (Table 1). For future reference, this cytochrome was designated MmcA (membrane multiheme cytochrome A). Multiheme c-type cytochromes are of particular interest as potential electron carriers in extracellular electron transport because of the well-documented role of multiheme c-type cytochromes in bacteria such as Shewanella and Geobacter species that are highly effective in extracellular electron transfer (21–23). MA3739, a gene coding for a five-heme c-type cytochrome, was transcribed at similar levels as mmcA, and 4.1-fold-higher expression was detected in AQDS-reducing than methanogenic cells (Table 1).

There are three other putative c-type cytochrome genes in the M. acetivorans genome (26). MA0167, which encodes a monoheme cytochrome with predicted localization in the cell membrane, was six times more highly expressed in cells grown via AQDS respiration (Table 1). Functional analysis of the outer membrane of G. sulfurreducens has suggested that a monoheme c-type cytochrome may play a role in regulating the expression of multiheme c-type cytochromes, possibly by providing a sensor function (34, 35). It is possible that the protein encoded by MA0167 plays a similar role in M. acetivorans. The expressions of MA2925 and MA2908, both of which encode two-heme c-type cytochromes, were comparable in AQDS-reducing versus methanogenic cells (Table 1). These cytochromes are homologous to methylamine utilization protein G (MauG) and the diheme cytochrome c peroxidase (CcpA). MauG is required for aerobic methylamine metabolism (36–38), and CcpA proteins reduce hydrogen peroxide to water and protect the cell from reactive oxygen species (39, 40). Thus, it seems unlikely that either of these cytochromes is involved in extracellular electron transfer.

In order to evaluate the potential role of c-type cytochromes in AQDS reduction, deletion mutant strains were constructed in M. acetivorans for each c-type cytochrome gene in the genome (Table 1). Only the deletion of mmcA inhibited AQDS reduction (Fig. 2A). Deletion of mmcA had a slight impact on methanogenic growth with

Notes: Cells were grown with methanol provided as the electron donor and AQDS as the electron acceptor in the presence of BES or were grown via methanogenesis with methanol as the substrate. Genes were only considered differentially expressed if the P value and FDR (false discovery rate) were ≤0.05. NS, no significant difference in read abundance between conditions.

That is, in AQDS/BES versus methanogenesis.
methanol (Fig. 2B). These results suggest that MmcA is a major component for extracellular electron transfer to AQDS but not for the conversion of methanol to methane.

Previous studies have suggested that MmcA is part of the Rnf complex, which is required for acetoclastic methanogenesis (41), and that mmcA is cotranscribed with Rnf genes located in the same region of the chromosome (42). However, deletion of the MmcA gene did not substantially impact growth on acetate (Fig. 2B) or transcription of other genes from the Rnf complex (Fig. S2). Furthermore, the expression profiles of mmcA and genes for the Rnf complex were also different (Tables 1 and 2).

Model for electron transport to AQDS via MmcA. MmcA is a strong candidate for the terminal AQDS reductase because its localization in the cell membrane (42) is likely to provide access to AQDS and because of the well-known role of outer-membrane multiheme c-type cytochromes in reduction of AQDS and various forms of Fe(III) in Gram-negative bacteria such as Shewanella and Geobacter species (21–23, 43). It was previously suggested that MmcA could be a terminal reductase for the reduction of soluble Fe(III)-citrate, based on the in vitro oxidation of MmcA in membrane vesicles upon addition of Fe(III)-citrate (31). Such in vitro assays can be poor predictors of in vivo activity because Fe(III)-citrate typically oxidizes c-type cytochromes in vitro, regardless of physiological function, due to its very positive redox potential. However, as detailed below, multiple lines of evidence support a model in which energy can be conserved during AQDS reduction.

*That is, in AQDS/BES versus methanogenesis.
when MmcA serves as the terminal reductase during in vivo methanol oxidation coupled to AQDS reduction (Fig. 3).

During methane production from methanol, methanol is converted to CH$_3$-CoM by the activity of three enzymes, methyltransferase 1 (MtaB), methyltransferase 2 (MtaA), and methanol corrinoid protein (MtaC) (44–46). The oxidation of one molecule of CH$_3$-CoM to CO$_2$ generates the reducing equivalents necessary to reduce three molecules of CH$_3$-CoM to methane. During methanol oxidation coupled to AQDS reduction in the presence of BES, the step that reduces CH$_3$-CoM to methane is blocked, but the option for CH$_3$-CoM oxidation remains (Fig. 3). Genes coding for enzymes involved in the oxidation of CH$_3$-CoM to carbon dioxide were more highly expressed in methanogenic cells, consistent with increased transcription of growth-related genes in methanogenic cells and the need for this pathway to generate reductants to support methanogenesis (Table S2).

Differential expression of genes encoding isomers of MtaB, MtaA, and MtaC suggested that there might be some differences in the route for methanol conversion to CH$_3$-CoM (Table 3). The genes for the isomers MtaB1, MtaA1, and MtaC1 were more highly transcribed in methanogenic cells, whereas AQDS-respiring cells had greater expression of genes coding for the alternative MtaB, MtaA, and MtaC isomers (Table 3). Differences in the activity of these isomers are unknown, but in previous studies mtaA1, mtaB1, and mtaC1 genes were highly transcribed during methanogenesis from methanol and MtaA1 was required for growth on methanol, whereas MtaA2 was dispensable (46).

Oxidation of methanol to carbon dioxide is expected to yield reduced ferredoxin and reduced F$_{420}$ (F$_{420}$H$_2$). It is likely that the Rnf complex oxidizes reduced ferredoxin with electron transfer to MmcA (47). Transcripts for genes coding for components of the Rnf complex were slightly higher (~1.5-fold) than those in methanogenic cells (Table 2), suggesting an important role for the Rnf complex in energy conservation from methanol oxidation coupled to AQDS reduction.
In methanogenic cells, the membrane-bound Fpo complex (F420:methanophenazine oxidoreductase) oxidizes F420H2 derived from methanol oxidation with the reduction of methanophenazine and proton translocation (48–52). Transcription of all Fpo subunit genes was higher in methanogenic cells than AQDS-reducing cells, as expected because of the importance of Fpo in oxidizing F420H2 in cells producing methane (Table S3). However, all of the Fpo complex genes were also being actively expressed in AQDS-respiring cells, suggesting that Fpo is important for the oxidation of F420H2 generated in methanol-oxidizing, AQDS-reducing cells. The reduced methanophenazine that Fpo generates from F420H2 oxidation could transfer electrons to MmcA (41, 42, 47, 53). Although it has also been proposed that reduced methanophenazine may be able to directly transfer electrons to extracellular electron carriers in M. acetivorans (31), the requirement for MmcA for growth via AQDS reduction indicates that this is an unlikely route for AQDS reduction.

In methanogenic cells, reduced methanophenazine could also donate electrons to the membrane-bound heterodisulfide reductase HdrDE (52, 54–59). In vitro evidence with membrane vesicles suggested that HdrDE can reduce AQDS with CoM-SH and CoB-SH oxidation to form CoM-S-S-CoB (31). However, the redox-active components of HdrE and HdrD responsible for electron transfer to an electron acceptor are embedded in the membrane and the cytoplasm, respectively (52), and thus unlikely to access extracellular AQDS in vivo. The relative expressions of hdrD and hdrE were slightly lower in AQDS-reducing cells than in methanogenic cells (Table S2). Furthermore, the inability of the MmcA-deficient strain to grow via AQDS reduction indicates that HdrDE is not capable of functioning as the sole AQDS reductase to support growth. Thus, based on the lack of strong evidence for a role for HdrDE, the likely simpler and more direct route for AQDS-dependent oxidation of reduced methanophenazine is electron transfer to MmcA.

Based on these considerations and current understanding of the function of the redox proteins involved (52, 60, 61), it is apparent that a net positive export of Na+/H+ outside the cell membrane during AQDS respiration that can support the generation of ATP is feasible (Fig. 3). In this model, two Na+ must be translocated into the cell for the initial oxidation of CH3-S-CoM (62–64). Two moles of F420H2 and one mole of reduced ferrodoxin are generated per mole of CH3-S-CoM oxidized to carbon dioxide. Fpo oxidizes the F420H2 with H+/H2O translocation and the reduction of methanophenazine (49–51). The reduced methanophenazine transfers electrons to MmcA, which reduces

bThat is, in AQDS/BES versus methanogenesis.
AQDS. The Rnf complex oxidizes the reduced ferredoxin coupled with Na\(^+\) translocation (41, 47, 65) and the reduction of MmcA. MmcA may transfer protons, as well as electrons during AQDS reduction, as observed in other c-type cytochromes (66–71). The ATP synthase couples both Na\(^+\) and H\(^+\) transport to ATP synthesis (72), but the H\(^+\)/Na\(^+\) antiporter complex Mrp can be important for balancing external Na\(^+\)/H\(^+\) ratios (73). Genes for Mrp were highly expressed in AQDS-reducing cells (Table 2).

Uncertainties in the stoichiometry of Na\(^+\)/H\(^+\) transport per ATP synthesized and the total amount of H\(^+\) translocated prevent an accurate estimate of the theoretical ATP yield per mole of methanol oxidized with the reduction of AQDS. However, the proposed metabolic route suggests a likely mechanism for net ATP synthesis to support the observed growth of *M. acetivorans* with methanol oxidation coupled to AQDS reduction.

**Implications.** The discovery that *M. acetivorans* can conserve energy to support growth from the oxidation of a one-carbon compound coupled to the reduction of an extracellular electron acceptor has important implications for the biogeochemistry of anaerobic soils and sediments and provides a genetically tractable model microbe for further analysis of the mechanisms of extracellular electron transfer in Archaea. Humic substances and Fe(III) are often abundant extracellular electron acceptors in a wide variety of anaerobic soils and sediments, and their availability for microbial respiration can reduce the extent of methane production (74–77). Competition for electron donors between methanogens and Fe(III)- and humic-reducing microorganisms is one factor (78–80). However, the finding that some methanogens may conserve energy by reducing extracellular electron acceptors suggests a mechanism for methanogens to survive in environments in which Fe(III) and oxidized forms of humic substances are abundant and then rapidly switch to methane production as these extracellular electron acceptors are depleted.

A comprehensive survey of the ability of diverse methanogens to conserve energy to support growth from electron transport to extracellular electron acceptors is warranted. Most methanogens, including other *Methanosarcina* species, lack membrane-bound multiheme cytochromes like MmcA and would need other mechanisms for extracellular electron transfer. The findings that MmcA is not essential for methane production and that expression of *mmcA* was increased when AQDS served as an electron acceptor suggest that the primary role of MmcA is extracellular electron transfer. If so, the presence of MmcA further suggests that there are environments in which the capacity for extracellular electron transfer substantially benefits *M. acetivorans*.

A wide diversity of archaea are capable of extracellular electron transfer (81). For archaea such as *Ferroglobus placidus* (24), *Geoglobus ahangari* (25), and diverse ANME (13–19), it has been proposed that outer-membrane cytochromes are the terminal reductase. It also appears that methanogens have evolved efficient means of extracellular electron transport; however, the mechanisms are poorly understood. The rapid nonphysiological reduction of extracellular electron acceptors by a range of redox-active proteins and cofactors *in vitro* necessitates genetically tractable model organisms for physiologically relevant functional studies. Thus, *M. acetivorans* may serve as an important model organism for better understanding cytochrome-based extracellular electron transfer in Archaea.

**MATERIALS AND METHODS**

**Strains and growth conditions.** *Methanosarcina acetivorans* strains were routinely cultured under strict anaerobic conditions at 37°C in a previously described (27) medium with either 8.5 mM methanol or 40 mM acetate provided as the substrates.

*M. acetivorans* mutant strains were constructed with *M. acetivorans* WWM1 (Δ*hpt*) (82) as the parent strain, as described previously (28). For the construction of MA0658, MA3739, MA2908, MA0167, and MA2925 deletion strains, genes were replaced with the *pac* gene (puromycin resistance gene). First, regions 500 to 1,000 bp upstream and downstream from the target genes were amplified by PCR (see Table S4 and Fig. S4 in the supplemental material). The DNA fragments of the upstream and downstream regions of MA0658 were digested with SacI/XbaI and EcoRI/XhoI. Upstream and downstream regions of MA3739 were digested with SalI/XbaI and SacI/NotI. Upstream and downstream regions of MA2908, MA0167, and MA2925 were digested with XhoI/HindIII and BamH1/NotI. The upstream fragment was ligated into the pJK3 plasmid (27). The downstream fragment was ligated into the pJK3 plasmid already containing the upstream fragment. This recombinant plasmid was then linearized and used for trans-
formation. The deletion and replacement of all genes with pac was verified with primers (Table S4). All transformants were selected on medium supplemented with puromycin (2 μM final concentration), as previously described (27).

Additions of anthraquinone-2,6-disulphonate (AQDS) were made from a concentrated stock to provide a final concentration of 16 mM. Cysteine was omitted from all cultures. When noted, 2-bromoethanesulfonate (BES) was added from a concentrated stock to provide a final concentration of 15 mM. Growth with AQDS was measured by determining numbers of cells stained with acridine orange with epifluorescence microscopy (83). For comparing methanogenic growth in wild-type and mutant cells, growth was monitored by spectrophotometry at an absorbance of 600 nm (84).

Analytical techniques. Methanol concentrations were monitored with a gas chromatograph equipped with a headspace sampler and a flame ionization detector (Clarus 600; Perkin-Elmer, Inc., San Jose, CA). Methane in the headspace was measured by gas chromatography with a flame ionization detector (Shimadzu, GC-8A) as previously described (85). The production of reduced AQDS reduction was monitored by spectrophotometry at an absorbance of 450 nm as previously described (86).

RNA extraction. Cells were harvested from triplicate 50 ml cultures of M. acetivorans grown with methanol (10 mM) provided as the electron donor and AQDS (16 mM) in the presence of the methanogenesis inhibitor BES (15 mM) or via methanogenesis with 40 mM methanol provided as the substrate. Cells were harvested when AQDS-respiring cultures had reduced ~8 mM AQDS (midxponential phase) and when methanogenic cells reached an optical density at 600 nm of 0.5.

Cells were split into 50 ml conical tubes (BD Sciences), mixed with RNAProtect (Qiagen) in a 1:1 ratio, and pelleted by centrifugation at 3,000 × g for 15 min at 4°C. Pellets were then immediately frozen in liquid nitrogen and stored at −80°C. Total RNA was extracted from all six cell pellets according to the previously described protocol (87) and cleaned using an RNeasy mini kit (Qiagen). All six RNA samples (three AQDS-respiring and three methanogenic) were then treated with Turbo DNA-free DNase (Ambion, Austin, TX). In order to ensure that samples were not contaminated with genomic DNA, PCR with primers targeting the 16S rRNA gene was done with RNA that had not been reverse transcribed. Further enrichment of mRNA was done with the MICROBExpress kit (Ambion), according to the manufacturer’s instructions.

RT-PCR analysis. Total RNA was prepared from M. acetivorans hpt and ΔMA0658 strains grown methanogenically with acetate (40 mM). Complementary DNA (cDNA) was prepared by reverse transcription with AMV reverse transcriptase (New England Biolabs, Ipswich, MA) with the primers TCAGCATGCCTTAACGTC (MA0664) or TCGCAGACAGCCTTAACGTC (MA0664) according to the manufacturer’s specifications. This cDNA was then used as a template for PCR with the following primers: CAGTGACC TGCCTCATTCCAAC (MA0659) or TCGCAGACAGCCTTAACGTC (MA0664). The amplified fragments were analyzed by agarose gel electrophoresis.

Illumina sequencing and data analysis. Directional multiplex libraries were prepared with the ScriptSeq v2 RNA-Seq Library preparation kit (Epicentre), and paired-end sequencing was performed on the Hi-Seq 2000 platform at the Deep Sequencing Core Facility at the University of Massachusetts Medical School in Worcester, MA.

All raw data generated by Illumina sequencing were quality checked by visualization of base quality scores and nucleotide distributions with FASTQC (http://www.bioinformatics.babraham.ac.uk/projects/fastqc/). Initial raw nonfiltered forward and reverse sequencing libraries contained an average of 134,187,478 ± 20,358,059 reads that were ~100 bp in length (Table S5). Sequences from all of the libraries were trimmed and filtered with Trimmomatic (88), with the sliding window approach set to trim bases with quality scores lower than 3, strings of 3 or more N’s, and reads with a mean quality score lower than 20. Bases were also cut from the start and end of reads that fell below a threshold quality of 3, and any reads smaller than 50 bp were eliminated from the library. These parameters yielded an average of 90,596,717 ± 23,433,670 quality reads per RNA-Seq library.

All paired-end reads were then merged with FLASH (89), resulting in 40,312,494 ± 8,686,910 reads with an average read length of 145 bp. After merging the QC-filtered reads, SortMeRNA (90) was used to separate all rRNA reads from nonribosomal reads, and this resulted in 30,679,551 ± 6,275,120 mRNA reads.

Mapping of mRNA reads. Trimmed and filtered mRNA reads from the triplicate samples for the two different culture conditions were mapped against the M. acetivorans strain C2A genome (NC_003552) downloaded from IMG/MER (img.jgi.doe.gov) using ArrayStar software (DNAStar). Analyses of reads from all three biological replicates for each condition demonstrated that the results were highly reproducible (Table S5 and Fig. S5).

Reads were normalized and processed for differential expression studies using the edgeR package in Bioconductor (91), with AQDS/BES considered the experimental condition and methanol the control. Genes with P values of ≤0.05 were considered differentially expressed. Using these criteria, 1,188 genes were downregulated, 2,121 genes were not differentially expressed, and 1,182 genes were upregulated (Table S1).

Genome data analysis. Gene sequence data for M. acetivorans C2A was acquired from the U.S. Department of Energy Joint Genome Institute (http://www.jgi.doe.gov) or from GenBank at the National Center for Biotechnology Information (NCBI; https://www.ncbi.nlm.nih.gov). Initial analyses were done with tools available on the Integrated Microbial Genomes (IMG) website (img.jgi.doe.gov). Some protein domains were identified with NCBI conserved domain search (92) and Pfam search (93) functions. Transmembrane helices were predicted with TMPred (94), TMHMM (95), and HMMTOP (96), and signal peptides were identified with PSORTB v3.0.2 (97) and Signal P v4.1 (98).

Data availability. Illumina sequence reads have been submitted to the SRA NCBI database under BioProject PRJNAS09433 and Biosample SAMN10580613 (SRX5113605 to SRX5113610).
