Abstract: We study renormalization group flows between six-dimensional superconformal field theories (SCFTs) using their geometric realizations as singular limits of F-theory compactified on elliptically fibered Calabi-Yau threefolds. There are two general types of flows: one corresponds to giving expectation values to scalars in the tensor multiplets (tensor branch flow) realized as resolving the base of the geometry. The other corresponds to giving expectation values to hypermultiplets (Higgs branch flow) realized as complex structure deformations of the geometry. To corroborate this physical picture we calculate the change in the anomaly polynomial for these theories, finding strong evidence for a flow from a UV fixed point to an IR fixed point. Moreover, we find evidence against non-trivial dualities for 6D SCFTs. In addition we find non-trivial RG flows for theories realizing small $E_8$ instantons on ALE spaces.

1 Introduction

One of the central concepts in the study of quantum field theory is renormalization group (RG) flows between different theories. This is especially important in the context of conformal field theories (CFTs) which correspond to fixed points of the renormalization group equations. Given two CFTs, a natural question to ask is whether there is a corresponding RG flow which connects two theories. In general terms, these flows are triggered either by an operator perturbation of the original UV CFT, or by a non-zero operator vev.

In this note we study the question of RG flows for six-dimensional SCFTs, i.e those with at least eight real supercharges. The best evidence for the existence of these theories comes from string theory [1–14], and recently a classification of 6D SCFTs which can be generated by string compactification has been achieved [15–21]. Given this list of theories, it is natural to ask about RG flows which can potentially connect these theories together.

The classification results of reference [20] rely on the F-theory realization of these theories. To make an SCFT, we start with F-theory on an elliptically fibered Calabi-Yau threefold $X$ with the base $B$ a non-compact Kähler surface. By simultaneously contracting $\mathbb{P}^1$’s of this geometry, we reach a conformal fixed point. Reference [20] determined all possible configurations of curves which can simultaneously contract, and moreover, all possible ways to generate an elliptic fibration over a given base.

The geometric characterization also provides insight into the moduli space of these theories. Indeed, starting from a smooth Calabi-Yau geometry, we reach a conformal fixed point by taking a singular limit in the Calabi-Yau moduli space. At a smooth point in the
moduli space, the basic moduli of our theory organize according to scalars in tensor multiplets and scalars in hypermultiplets. The geometric interpretation of the tensor multiplet scalars is simply the volumes of the \( \mathbb{P}^1 \)'s of the base. Complex structure moduli correspond to complex scalars of the effective theory, and as such fill out half of the scalar degrees of freedom of a \((1,0)\) hypermultiplet in six dimensions.\(^1\) Going to a singular point in the geometric moduli space corresponds to proceeding to the UV.

To study flows between SCFTs, we can therefore start with a singular geometry (i.e. a UV SCFT), and then activate vevs for scalar operators of the theory. This triggers a flow to a new theory, leading us to a geometry which may still be singular (and thus an IR SCFT). Our task therefore reduces to correctly identifying which deformations of the geometry actually correspond to operator vevs.

In order to corroborate our picture of flows between theories, we perform various checks on the match with geometry. First of all, we show that the resulting moduli are associated with normalizable modes of the effective field theory. Additionally, we need to be able to quantitatively compare the number of degrees of freedom present in a 6D SCFT. Along these lines, we use the recently developed methods of references \([23, 24]\) to compute anomaly polynomials for 6D SCFTs to compare candidate SCFTs. A specific difference in the value of the anomaly polynomial, consistent with ‘t Hooft anomaly matching conditions \([24, 25]\) is a strong indication that there is an RG flow. Since we can also typically identify which theory is associated with a more singular point in moduli space, we also have a clear indication about how we can flow from the UV to the IR.

Using anomaly polynomials in the context of a number of examples leads us to a surprising conclusion that there apparently are no dualities for \((1,0)\) SCFTs. In particular we show that candidate dual theories have distinct anomaly polynomials ruling them out as duals of one another. This observation suggests that the classification of \([20]\) does not need to be modded out by duality equivalences. We also study a class of models from reference \([20]\), associated with the dual F-theory description of heterotic instantons probing an ADE singularity. For a fixed choice of boundary data for the heterotic instanton, we find that there are a number of dual F-theory models. We present an explicit hierarchy of flows between theories with given boundary data. The full moduli space therefore assembles according to a partially ordered set dictated by RG flows and we find a single class of theories related by RG flows for each class of asymptotic bundle data for the heterotic string.

The rest of this note is organized as follows. First in section 2 we provide some more details on the general expected correspondence between deformations of an F-theory geometry and the associated flows in moduli space. We then turn in section 3 to quantitative checks on this picture, focussing on the role of the anomaly polynomial for a 6D SCFT, and how it tracks details of flows between theories. In section 4 we give several illustrative examples of both tensor branch and Higgs branch flows. We conclude in section 5.

\(^1\)The scalars of the hypermultiplet moduli are captured by the complex structure moduli, as well as the intermediate Jacobian of the Calabi-Yau threefold. Owing to the fact that there is an SU(2) R-symmetry which acts on the tangent space to the hypermultiplet moduli space, we shall often simply speak of the complex structure moduli as indicating the presence of hypermultiplet moduli. This observation turns out to be quite important in the analysis of the limiting behavior of T-brane solutions \([22]\).
2 Geometry of 6D RG flows

In this section we discuss in more detail the sense in which deformations in the geometry of an F-theory compactification can be translated into vevs of operators in a 6D SCFT. To frame our discussion we shall often consider F-theory on an elliptically fibered Calabi-Yau threefold $X \to B$. To make an SCFT, it suffices to consider $B$ a non-compact Kähler surface such that all rational curves are simultaneously contractible in the Kähler cone. The SCFT point corresponds to this singular limit where the volumes of all curves have shrunk to zero size. The data specifying an F-theory compactification is given by sections $f$ and $g$ of $O_B(-4K_B)$ and $O_B(-6K_B)$, respectively, leading to an associated Calabi-Yau threefold whose (minimal) Weierstrass form is:

$$y^2 = x^3 + fx + g.$$  \tag{2.1}

In the special case of an SCFT, the minimal Weierstrass equation will typically be quite singular. To make sense of the physical model, we consider blowups of the geometry and/or smoothing deformations to reach a less singular geometry. For example, if we have a collection of curves in the base where the Kodaira-Tate fiber becomes too singular, we will need to perform blowups in the base. If no finite sequence of blowups is available, we will discard the putative F-theory model.

Since being able to reach a smooth geometry ensures the existence of an F-theory model, we can also choose to reverse the above procedure: We can start from a smooth Calabi-Yau $\tilde{X}$ and then take a degeneration limit either in Kähler moduli or complex structure moduli. In this sense, we can consider various intermediate stages before reaching the maximally singular case of equation (2.1). For example, we can work over a smooth base, but allow degenerations in the elliptic fiber, or conversely, we can consider a singular base, but with a smooth fiber. In some cases, the data of the base and fiber are correlated and cannot be disentangled.

Suppose then that we are working with an F-theory model given by a smooth base $B$, and an associated elliptic fibration with smooth total space and all fibers having dimension one. There is then a well-defined prescription for extracting the 6D effective field theory for this system. The field content will consist of some number of tensor multiplets, hypermultiplets, and vector multiplets. The Kähler parameters of the base $B$ correspond to background vevs for the real scalars of the tensor multiplet, and the complex structure moduli correspond to half of the vevs for the hypermultiplets.

More precisely, we need to know which of the geometric deformations actually translate to physical parameters of our system. These are described by the normalizable deformations, namely those with finite non-zero kinetic terms at a smooth point of the moduli space. Letting $\delta J_{(1,1)}$ denote variations of the Kähler form and $\delta \Omega_{(2,1)}$ denote the variations of the holomorphic three-form, we need to ensure that:

$$\int_B \delta J_{(1,1)} \wedge \delta J_{(1,1)} < \infty \quad \text{and} \quad \int_{\tilde{X}} \delta \Omega_{(2,1)} \wedge \delta \Omega_{(1,2)} < \infty.$$  \tag{2.2}

In the latter case, note that we also need to pick a resolution $\tilde{X} \to X$ of the singular Calabi-Yau $X$ to carry out the integral.
Such normalizable modes specify deformations of the effective field theory. By tuning their values, we can reach singular points of the moduli space, i.e. where we have a 6D SCFT. A geometric criterion for identifying which complex structure limits of Calabi-Yau threefolds are at finite distance in the moduli space (and hence represent normalizable modes) was found in \[26, 27\]: the singularities must be so-called “canonical singularities.” Moreover, the techniques of \[28\] can be used to show that these are the same singularities which can be resolved after blowing up the base of an elliptic fibration.

Of course, in physical terms we start at the most singular geometries and then proceed to activate vevs for operators to flow to new IR fixed points. A common feature of such flows is that starting from a UV fixed point, a flow to the infrared can sometimes lead to completely decoupled CFTs in the IR:

\[
CFT_{UV} \rightarrow CFT_{IR}^{(1)} \sqcup \cdots \sqcup CFT_{IR}^{(m)}. \tag{2.3}
\]

(The “disjoint union” symbol \(\sqcup\) is used to denote decoupled theories.) When the context is clear, we shall sometimes omit these additional decoupled sectors. However, to properly match all UV and IR anomalies, we must include all such sectors.

In geometric terms, there are two ways for us to trigger a flow, corresponding to Kähler deformations and complex structure deformations (i.e. smoothings). Physically, the Kähler deformations trigger tensor branch flows and the complex structure deformations trigger Higgs branch flows. We can also have various mixed branch flows obtained by combining these two basic operations. Indeed, these two branches of moduli space can intersect along lower-dimensional subspaces.

The case of activating Kähler parameters is by now well-known, and corresponds to giving tension to at least some subset of strings of a theory. For example, we can flow between the different \(A_N\) \((2,0)\) theories by starting with a configuration of \(N\) collapsed \(-2\) curves in a base \(B\):

\[
A_N\ (2,0)\ \text{theory}: \underbrace{2, \ldots, 2}_N \tag{2.4}
\]

Resolving these curves from left to right in the associated Dynkin diagram triggers a sequence of flows:

\[
A_N \xrightarrow{RG} A_{N-1} \sqcup T_{(2,0)} \xrightarrow{RG} \cdots \xrightarrow{RG} A_1 \sqcup (T_{(2,0)})^{\sqcup (N-1)}, \tag{2.5}
\]

where at each stage of this resolution process, we have some additional decoupled \((2,0)\) tensor multiplets, each of which we denote as \(T_{(2,0)}\). In the M-theory description, we are pulling apart a stack of \(N\) M5-branes one at a time. In this sense, the \(A_N\) theory is in the UV and the \(A_1\) theory with \((N-1)\) decoupled \((2,0)\) tensor multiplets is in the IR.

As another class of examples, we can consider starting from the rank \(N\) E-string theory:

\[
\text{rank } N\ \text{E-string theory}: \underbrace{1, 2, \ldots, 2}_N. \tag{2.6}
\]

Note that here we can either flow to a lower rank E-string theory (i.e. by resolving the \(-2\) curve on the right to finite size), or we can flow to an \(A\)-type \((2,0)\) theory. Again, the M-theory description is helpful in tracking the various decoupled SCFTs in the infrared.
Now, in addition to motion in the Kähler moduli space, we can also study complex structure deformations by activating vevs for the operators parameterizing the Higgs branch. Some of these cases have a clear interpretation in terms of a weakly coupled Lagrangian description. For example, consider the local model for the collision of a non-compact curve of $A_N$ singularities with a non-compact curve of $A_M$ singularities. Letting $u = 0$ and $v = 0$ denote the corresponding loci, a local model for the Calabi-Yau threefold is:

$$y^2 = x^2 + u^N v^M.$$  \hspace{1cm} (2.7)

In physical terms, there is a collection of $N \times M$ bifundamental hypermultiplets trapped at the intersection point $u = v = 0$. We can move onto the Higgs branch by activating a vev for these hypermultiplets. Assuming without loss of generality that $N \leq M$, the deformed geometry takes the form [29]:

$$y^2 = x^2 + v^{M-N} \prod_{i=1}^{N} (uv - t_i),$$  \hspace{1cm} (2.8)

i.e. we break $\text{SU}(N) \times \text{SU}(M)$ to $\text{SU}(M-N)$. The parameters $t_i$ are specified by the vevs of the hypermultiplets. More precisely, we can, by a choice of appropriate flavor rotation view the hypermultiplets as transforming in the adjoint representation of the diagonal $\text{SU}(N)_{\text{diag}} \subset \text{SU}(N) \times \text{SU}(M)$. The unfolding parameters for the corresponding singularity then follow the standard rules for geometric engineering.

We can also produce an interacting fixed point by gauging some of our symmetries. For example, to gauge the $\text{SU}(N)$ subgroup of the $\text{SU}(N) \times \text{SU}(2N)$ global symmetry of a theory with $N \times 2N$ bifundamental hypermultiplets, we can consider an $\text{SU}(N)$ gauge theory on a curve of self-intersection $-2$. Such a theory must include $2N$ flavors in order to satisfy the anomaly cancellation conditions for the gauge symmetry, so it has a flavor symmetry of $\text{SU}(2N)$ (while the $\text{SU}(N)$ factor has been gauged).

We can now move onto a partial Higgs branch of this theory, breaking the gauge symmetry to $\text{SU}(N-1)$. The resulting theory consists of the gauge theory sector, as well as $2N - 1$ hypermultiplets which are singlets under this gauge symmetry. The full Higgs branch flow is then:

$$[\text{SU}(2N)] \text{SU}(N) \xrightarrow{\text{RG}} [\text{SU}(2N-2)] \text{SU}(N-1) \sqcup (2N-1) \text{ singlets},$$ \hspace{1cm} (2.9)

where here, the group in square brackets denotes the flavor group.

More generally, however, there need not exist a weakly coupled interpretation of these operator vevs. To give examples along these lines, consider the case of a conformal matter sector (in the sense of [17, 18]) localized at the intersection of two $E_8$ seven-branes respectively located at $u = 0$ and $v = 0$:

$$y^2 = x^3 + u^5 v^5.$$ \hspace{1cm} (2.10)

There is conformal matter localized at $u = v = 0$. From this singular model, we can either move onto the tensor branch, or onto the Higgs branch. Moving onto the tensor branch
amounts to introducing a sequence of blowups of the singular point of the base. We must continue to blowup until the elliptic fiber over each blown up curve is in Kodaira-Tate form. As first derived in reference [12], this leads to a sequence of eleven blowups, leading to the geometry:

\[ [E_8] \oplus [E_8] \simeq [E_8]1, 2, 2, 3, 1, 5, 1, 3, 2, 2, 1|E_8], \]  

(2.11)

where on the left side we have indicated the conformal matter by the symbol \( \oplus \), and on the right hand side we have indicated the explicit resolution of curves. The corresponding eleven volume moduli parameterize the tensor branch of the SCFT. One set of flows corresponds to having some subset of the volume moduli go to non-zero values. For example, we can initiate a flow by resolving the middle \(-5\) curve. When we do this, the two sequences of curves \(1, 2, 2, 3, 1\) and \(1, 3, 2, 2, 1\) decouple. Additionally, the theory on the \(-5\) curve decouples as another SCFT. This sector consists of an additional \((1, 0)\) tensor multiplet, and a gauge theory with gauge group \(F_4\). Now, an important feature of this gauge theory is that in the infrared, the value of its gauge coupling is formally zero, the reason being that the tensor multiplet scalar has picked up a formally infinite vev. This geometry corresponds, in the M-theory picture as having an M5-brane probing an \(E_8\) singularity [17] and the above tensor branches emerge from fractionating the M5-brane to 12 (or fewer) pieces.

Instead of considering a flow on the tensor branch, we can also consider complex deformations. For example, we can consider the partial unfolding to the model:

\[ y^2 = x^3 + (uv - \beta)^5. \]  

(2.12)

The parameter \(\beta\) is our complex structure modulus, and it corresponds to a brane recombination mode [17, 18]. Indeed, for generic \(\beta\), we have a single \(E_8\) seven-brane located at \(uv = \beta\). This generalizes the usual notion of Higgsing and brane recombination to the case of a conformal matter sector. In the M-theory picture (see figure 1) this corresponds to lifting off the M5-brane from the \(E_8\) singularity. The theory flows in the IR to a free theory of a single \((2, 0)\) tensor multiplet, i.e. the theory of an M5-brane away from the singularity.

Similar considerations also hold for the generalized quiver theories of the type encountered in [17, 18, 20]. For example, consider the case of a \(-2\) curve which supports an \(e_8\) fiber, which in turn intersects two non-compact \(E_8\) seven-branes according to the diagram:

\[ [E_8] \oplus \frac{e_8}{2} \oplus [E_8]; \]  

(2.13)

the corresponding M-theory picture is given by having two M5-branes probing the \(E_8\) singularity, (see figure 2a). This leads to two \((E_8, E_8)\) conformal matter sectors, one for each intersection of the \(-2\) curve with a non-compact seven-brane. If we expand the middle \(-2\) curve with \(e_8\) gauge symmetry to large size, we get a flow on the tensor branch to two decoupled \((E_8, E_8)\) conformal matter systems, a \((1, 0)\) tensor multiplet, and 248 free vector multiplets. Alternatively, we can flow on the Higgs branch by giving a vev to one such conformal matter sector. This initiates an unfolding, i.e. breaking pattern:

\[ [E_8] \oplus \frac{e_8}{2} \oplus [E_8] \rightarrow ([E_8] \oplus [E_8]) \sqcup T_{(2,0)}, \]  

(2.14)
Figure 1. M-theory realization of the flow from $E_8 \oplus E_8$ conformal matter to a single tensor multiplet. There is an M5-brane probing the $E_8$ singularity in the UV (left), which lifts off the singularity in the IR (right).

(a) Two M5-branes on an $E_8$ singularity.

(b) One M5-brane lifted.

(c) Two M5-branes lifted.

Figure 2. Two M5-branes probing an $E_8$ singularity. The theory flows from (a) to (b) to (c).

which in the M-theory picture corresponds to lifting one M5-brane off the singularity (see figure 2b). Physically, activating a vev for the conformal matter initiates a breaking pattern to the diagonal $E_8$ subgroup of $[E_8] \times e_8$. As one of the groups participating in the Higgsing is a flavor symmetry, the unbroken symmetry group is also ungauged (i.e. at arbitrarily small gauge coupling). One can also lift both M5-branes together, which makes the theory flow to the $A_1 (2,0)$ theory (see figure 2c).

3 Anomaly polynomial analysis

In the previous section we presented a general description of possible flows between 6D theories, using the geometry as a guide to possible operator vevs, i.e. flows on the tensor branch and/or generalized Higgs branch. In general, however, it can be mathematically
challenging to determine when a given complex structure deformation corresponds to a normalizable mode of the physical theory. Indeed, precisely because our defining geometries are so singular, specifying what counts as a “lower order deformation” which can initiate a flow is a rather subtle question.

To complement this perspective, we can also study the anomalies of global symmetry currents of our system. A change in the anomaly polynomial after applying a geometric deformation is a strong indication that this deformation has initiated a flow to a new theory. Turning the discussion around, the analysis of anomalies can provide a good check on candidate normalizable deformations of a singular, non-compact model. In other words, comparison of anomalies gives us a highly non-trivial tool to assess whether two putative theories are related by an RG flow.

The anomalies of a 6D SCFT are conveniently captured in terms of the anomaly polynomial, i.e., a formal eight-form constructed from the background field strengths of the system. Since all gauge anomalies must cancel to have a consistent quantum theory, the main utility in the context of checking flows will center on the global symmetry currents. This includes the 6D spacetime diffeomorphisms associated with the tangent bundle $T$, the SU(2) $R$-symmetry which we associate with curvature $R$ in a background bundle, as well as curvatures $F_i$ in background bundles for any flavor symmetries which an SCFT may possess. The general structure of an anomaly polynomial will then be built out of the formal characteristic classes $p_1(T)$, $p_2(T)$, $c_2(R)$ and $c_2(F_i)$, where the $p$’s denote Pontryagin classes (i.e. $p_1$ is a four-form and $p_2$ is an eight-form) and the $c_2$’s denote second Chern classes (i.e. four-forms). Given an SCFT, we therefore get the anomaly polynomial:

$$I_{\text{SCFT}} = \alpha c_2(R)^2 + \beta p_1(T)^2 + \gamma c_2(R)p_1(T) + \delta p_2(T) + \sum_i \delta_i c_2(R)c_2(F_i) + \sum_i \gamma_i p_1(T)c_2(F_i) + \sum_i \kappa_i \delta_i c_2(F_i)c_2(F_i),$$  

where in our conventions $c_2(F) = \frac{1}{4}\text{Tr}F^2$, with $F$ the field strength. The terms of the first line are common to all 6D SCFTs. The terms of the second line depend on the details of the flavor symmetries present in a given theory.

In fact, even more is required in the difference $I_{\text{UV}} - I_{\text{IR}}$ of the anomaly polynomials for UV and IR SCFTs. If we restrict our analysis to symmetries which are common to the UV and IR theories, then the difference of the anomaly polynomials needs to be a perfect square \[^2\](by which we mean a quadratic form). The reason is that ’t Hooft anomaly matching for our theory can only proceed if there is an appropriate Green-Schwarz term available to compensate for this difference. This in turn requires factorization of the difference of the UV and IR anomaly polynomials into a perfect square. Since diffeomorphism invariance is always present, $p_1(T)$ also needs to appear in a perfect square. Additionally, since $p_2(T)$ can never factor to a perfect square, its coefficient in the anomaly polynomial

\[^2\]A word of caution to the reader. In the literature for supergravity models generated by F-theory compactifications, it is common to let $R$ refer to the “tangent bundle contributions” in the 6D effective theory, and to completely omit the contribution from the R-symmetry currents. The reason for this omission is simply that in all of these models gravity is dynamical and there is no SU(2) R-symmetry.
is the same in the UV and the IR. Further, if the R-symmetry is unbroken by a flow, then \( c_2(R) \) needs to appear in a perfect square.

Of course, in practice verifying the factorization condition for unbroken symmetries can turn out to be subtle. For example, when we initiate a flow to the infrared, we need to account for all possible decoupled SCFTs. Additionally, much as in the case of 4D SCFTs \([30]\), it is a priori possible that the infrared R-symmetry may mix with additional SU(2) flavor symmetries. Further, such flavor symmetries may only emerge in the infrared.

When we turn to examples of flows in section 4 we will indeed encounter various examples with emergent symmetries in the infrared.

The anomaly polynomial for all 6D SCFTs constructed via F-theory can be determined using the methods developed in references \([23, 24]\). Since we will be making heavy use of this result when we turn to examples, we shall spell out some additional details about how to algorithmically generate the anomaly polynomial of a 6D SCFT given an explicit F-theory model.

The basic philosophy of this approach hinges on two observations. First of all, since the real scalar of a tensor multiplet is neutral under the SU(2) R-symmetry, we can pass onto the tensor branch. By anomaly matching considerations, the anomaly polynomial on the tensor branch must match to that of the SCFT.\(^3\) The second observation is that in the special case where the number of tensor multiplets \( n_{\text{tensors}} \) is equal to the number of simple gauge group factors \( n_{\text{groups}} \), compatibility with the Green-Schwarz mechanism for the gauge group factors imposes a unique structure for the resulting anomaly polynomial.

In more detail, the anomaly polynomial has a one-loop contribution, as well as a contribution from the exchange of a tensor field. These two pieces combine as:

\[
I_{\text{tot}} = I_{\text{1-loop}} + I_{\text{GS}}.
\]  

\( (3.3) \)

For anomaly cancellation to work via the Green-Schwarz mechanism, we must demand that the one-loop contribution, to the anomaly polynomial factorizes for all of the gauge groups. For the flavor symmetry factors, however, no such factorization is necessary. So, in the special case where the number of tensor multiplets is the same as the number of simple gauge group factors, we can extract the total contribution to the anomaly polynomial by completing the square of the one-loop contribution.

In general, however, anomaly cancellation in a 6D SCFT only imposes the weaker condition that \( n_{\text{tensors}} \geq n_{\text{groups}} \). When we have more tensors than simple gauge groups, factorization alone does not dictate a unique answer. Examples of this type include the E-string theory, as well as theories containing E-strings interposed between simple gauge group factors:

- E-string Theory: 1, 2, ..., 2
- Example Theory: \( \mathfrak{e}_8 \), \( \mathfrak{sp}_1 \), \( \mathfrak{g}_2 \)

\( (3.4) \)

\( (3.5) \)

\(^3\)In analogy with the case of lower-dimensional examples, this of course assumes that there is no emergent SU(2) flavor symmetry which mixes with the putative R-symmetry.
where for the convenience of the reader we have indicated the gauge group / fiber type associated with each theory. Another class of examples are those which contain just $-2$ curves interposed between gauge group factors. Examples of this type include fiber enhancements over a chain of $-2$ curves:

$$A_3 \ (2,0) \ \text{Theory: \ } 2, 2, 2 $$

Fiber Enhanced Theory: $[SU(n)]^2, 2, 2, [SU(n)].$ \hspace{1cm} (3.6)

On the other hand, the anomaly polynomials for the $A_k \ (2,0)$ theories have been determined in references [31–33], and the rank $k$ E-string theory anomaly polynomial has been determined in reference [23]. This turns out to be enough to fix the form of the anomaly polynomial for all SCFTs which arise in F-theory. The main idea is that we interpret these theories without a simple gauge group factor as a generalized type of matter which is interposed between two gauge groups. In the example of line , we view the configuration 1, 2 as a generalized matter of both an $e_8$ gauge theory (the $-12$ curve) and an $sp_1$ gauge theory (the rightmost $-2$ curve). Viewing all such contributions as generalized matter, we have a system where the number of tensor multiplets matches to the number of simple gauge group factors.

Now, an important result from reference [20] is that all 6D SCFTs which arise in F-theory are of precisely the form which can be handled by the method of [24]. This means that to extract this data, it is enough for us to carefully take into account the contributions from these generalized matter contributions. Indeed, proceeding inductively, one can start building up larger structures which must also work in the same way. For example, the $(E_8, E_8)$ conformal matter of references [12, 17, 18] is a sequence of curves:

$$[E_8], 1, 2, 2, 3, 1, 5, 1, 3, 2, 2, 1, [E_8].$$ \hspace{1cm} (3.8)

So if our only concern is the contribution to the anomaly polynomial from the global symmetry currents, we can build up to larger structures in one shot rather than adding up the individual E-string theories and imposing factorization of the anomaly polynomial iteratively.

It is therefore enough for us to fix the contribution from these generalized types of matter, i.e., the contributions from the $A$-type $(2,0)$ theories and the rank $k$ E-strings which attach to simple gauge group factors.\footnote{We thank K. Yonekura for helpful discussions on this point.} The main subtlety we encounter in this procedure is the proper way to deal with the center of mass degrees of freedom for these SCFTs once we couple them to larger structures.

For example, in the case of the $(2,0)$ theory realized by $k$ M5-branes in flat space, there is an overall “center of mass degree of freedom” described by a free $(2,0)$ tensor multiplet. In terms of $(1,0)$ multiplets, this is is a single hypermultiplet and a $(1,0)$ tensor multiplet. By a similar token, when we consider the anomaly polynomial for a rank $k$ E-string theory, there is a hypermultiplet parameterizing the center of mass degree of freedom for the $k$ small instantons inside an $E_8$ wall. In F-theory language, this additional hypermultiplet corresponds to the point in the base where all the curves contract. Indeed,
the hypermultiplet center of mass degrees of freedom parameterizing the motion of the M5-branes and the E-strings transform as a half hypermultiplet in the doublet representation of SU(2)\textsubscript{L}, the factor appearing in the isometry group SO(4) \simeq (SU(2)\textsubscript{L} \times SU(2)\textsubscript{R})/\mathbb{Z}_2.

In what follows, we shall often make use of the following anomaly polynomials:

\[ I[k \text{ M5's}] = \frac{k^3}{24} (c_2(L) - c_2(R))^2 - kI_8 \]  
\[ I[k \text{ E-strings}] = \frac{k^3}{6} (c_2(L) - c_2(R))^2 + \frac{k^2}{2} (c_2(L) - c_2(R))I_4 + k \left( \frac{I_4^2}{2} - I_8 \right) \]  

The anomaly polynomial for M5-branes was obtained in reference [33] and that of the E-string theory was obtained in reference [23]. As in these references, we have introduced the specific combinations:

\[ I_4 = -\frac{1}{2} (c_2(L) + c_2(R)) + \frac{1}{4} (p_1(T) + \text{Tr} F_{E8}^2) \]  
\[ I_8 = \frac{1}{48} \left( (c_2(L) - c_2(R))^2 + p_2(T) - (c_2(R) + c_2(L) + \frac{1}{2} p_1(T))^2 \right). \]  

We have also included the flavor symmetry SU(2)\textsubscript{L} present for both the E-string theory and the M5-brane theory.

Now, an important subtlety in the F-theory realization of 6D SCFTs are curves which support a singular fiber which does not have a corresponding gauge group. Examples of this type include the configurations:

\[ I_{\frac{1}{2}}, \ldots, I_{\frac{1}{2}} \text{ and } II_{\frac{1}{2}}, \ldots, II_{\frac{1}{2}}. \]

Observe that this also occurs in the case of the example theory of line (3.5). The interpretation in F-theory of these cases was discussed at length in [20]. As explained there, the key point is that there will typically be some additional (half) hypermultiplets localized at the intersection points of the discriminant locus. Since we will frequently encounter situations like this in our analysis of anomaly polynomials, let us pause to explain how to properly account for these contributions.

In the case of enhancement to an \( I_1 \) fiber, there is indeed a sense in which we can interpret it as a single seven-brane wrapping the curve. That means that morally speaking, there is a \( u(1) \) gauge symmetry associated with it. On the other hand, it is well-known that in any non-compact F-theory model in six dimensions, such \( u(1) \) factors are always coupled to background two-form potentials, and are consequently eliminated by a generalized St"uckelberg mechanism. For the purposes of calculating an anomaly polynomial, however, we can still formally view the \( I_1 \) fiber as contributing an \( su_1 \) gauge symmetry. Factorization then proceeds as before.

In the case of an enhancement to a type \( II \) fiber, we have a strongly coupled bound state of seven-branes of different \( (p, q) \) type. For this reason, it is simpler to just study the net change in the number of hypermultiplets connected with the presence of such a fiber type.
3.1 Examples with E-strings

Let us illustrate these general considerations with a few examples. We mainly focus on variations connected with the E-string theory as this is the most common type of generalized matter we shall encounter. When a rank 1 E-string connects two matter curves of gauge group $G_L, G_R$ i.e., when the configuration takes the form

$$\ldots, G_L, \tfrac{1}{[G_M]}, G_R, \ldots$$

a $G_L \times G_R$ subgroup of $E_8$ is gauged, leaving a leftover global symmetry subgroup $G_M$, which may be trivial. This is accounted for by replacing

$$\text{Tr} F_{E_8}^2 \rightarrow \text{Tr} F_{G_L}^2 + \text{Tr} F_{G_R}^2 + \text{Tr} F_{G_M}^2 \quad (3.14)$$

Similarly, if the rank 1 E-string touches only a single curve carrying gauge group $G$, i.e.

$$\tfrac{1}{[G_M]}, G, \ldots$$

one replaces

$$\text{Tr} F_{E_8}^2 \rightarrow \text{Tr} F_{G}^2 + \text{Tr} F_{G_M}^2 \quad (3.15)$$

For the rank $k > 1$ E-strings, the same decomposition of the flavor symmetry also applies. However, the $c_2(L)$ dependence no longer drops out. Note that it is possible to gauge the $\text{SU}(2)_L$ symmetry of the rank 2 E-string, as discussed in [24]. In the F-theory picture, this gauging corresponds to a configuration:

$$\frac{H}{1 1 2} II^{ns} IV$$

Next, we must add in the anomaly polynomial contributions from the matter-namely those from any tensor multiplets, vector multiplets, or hypermultiplets. The tensor multiplets each contribute

$$I_{\text{tensor}} = \frac{c_2(R)^2}{24} + \frac{c_2(R)p_1(T)}{48} + \frac{23p_1(T)^2 - 116p_2(T)}{5760}. \quad (3.16)$$

The vectors of gauge symmetry $G$ contribute

$$I_{\text{vector}} = -\frac{\text{tr}_{\text{adj}} F^4 + 6c_2(R)\text{tr}_{\text{adj}} F^2 + d_Gc_2(R)^2}{24} - \frac{(\text{tr}_{\text{adj}} F^2 + d_Gc_2(R))p_1(T)}{48} - \frac{d_G7p_1(T)^2 - 4p_2(T)}{5760}. \quad (3.17)$$

Here, $d_G$ is the dimension of (the adjoint representation of) $G$. Furthermore,

$$\text{tr}_{\text{adj}} F^4 = t_G\text{tr}_{\text{fund}} F^4 + \frac{3}{4}u_G(\text{Tr} F^2)^2$$

and

$$\text{tr}_{\text{adj}} F^2 = h_G^\vee \text{Tr} F^2. \quad (3.19)$$

$h_G^\vee$ is the dual Coxeter number of $G$, and the values of the group theory constants $t_G, u_G$ can be found in appendix A of [24]. Similarly, recall that the contribution from a hypermultiplet in representation $\rho$ is

$$I_{\text{hyper}} = \frac{\text{tr}_\rho F^4}{24} + \frac{\text{tr}_\rho F^2p_1(T)}{48} + \frac{d_\rho7p_1(T)^2 - 4p_2(T)}{5760}. \quad (3.20)$$
For fundamental hypermultiplets
\[ \text{tr}_{\text{fund}} F^4 = \frac{3}{4} x_G (\text{Tr} F^2)^2 \] (3.21)

and
\[ \text{tr}_{\text{fund}} F^2 = s_G \text{Tr} F^2. \] (3.22)

The constants \( x_G \) and \( s_G \) can be found in appendix A of [24]. For hypermultiplets in other representations e.g. spinor representations, these group theory factors can be read off from table 2 of [34]. Although it is technically a special case of (3.20), it is useful to include the anomaly polynomial contribution for a hypermultiplet in a mixed representation \((\rho, \mu)\):
\[
I_{\text{mixed}} = \frac{d_{\mu} \text{tr}_\rho F^4_\rho + d_\rho \text{tr}_\mu F^4_\mu}{24} + \frac{(\text{tr}_\mu F^2_\mu)(\text{tr}_\rho F^2_\rho)}{4} + \frac{d_{\mu} (\text{tr}_\rho F^2_\rho) p_1(T) + d_\rho (\text{tr}_\mu F^2_\mu) p_1(T)}{48} + \frac{d_{\mu} d_\rho 7 p_1(T)^2 - 4 p_2(T)}{5760}. \] (3.23)

Finally, we must also add to the anomaly polynomial a Green-Schwarz term to cancel the gauge anomaly. From the above, we see that the anomaly polynomial may depend on the gauge field strength \( F \) through either \( \text{Tr} F^4 \) or \( \text{Tr} F^2 \). If there is an independent quartic Casimir invariant, the former can never be a perfect square, and so factorization of the anomaly polynomial is impossible unless all \( \text{Tr} F^4 \) terms drop out. Fortunately, this is guaranteed to occur provided the anomaly cancellations are imposed. As a result, for any 6D SCFT, it suffices to consider only the \( \text{Tr} F^2 \) dependence of the anomaly polynomial. In general, the anomaly polynomial takes the form,
\[
I_{1\text{-loop}} = a (\text{Tr} F^2)^2 + b (\text{Tr} F^2) + c \] (3.25)

for some rational number \( a \) and some functions \( b \) and \( c \) of \( c_2(R), p_1(T), p_2(T), \) and the field strengths of other gauge/flavor symmetries. Now, adding in the Green-Schwarz term to cancel the gauge dependent piece corresponds simply to completing the square in the variable \( \text{Tr} F^2 \). We are left with,
\[
I_{\text{tot}} = I_{1\text{-loop}} + I_{GS} = a (\text{Tr} F^2)^2 + b (\text{Tr} F^2) + c - a \left( \text{Tr} F^2 + \frac{b}{2a} \right)^2 \] (3.26)

If there are multiple gauge fields, the resulting expression \( c - \frac{b^2}{4a} \) will also be a quadratic polynomial in the traces of their squared-field strengths. As a result, we can simply repeat this procedure of completing the square to remove all gauge field strength dependence, and the result is the final expression for the anomaly polynomial of the theory.

4 Examples of RG flows

In this section we apply the technology of the anomaly polynomials reviewed above to study whether two theories are related by RG flow. From the F-theory setup we know two theories
could potentially be related by RG flow if they are connected by a change of parameters in the geometry. But even in such cases, it is often not very simple to determine if the two theories that are connected by a change of parameters are related by RG flows or if they are dual to one another and lead to equivalent conformal fixed points at the strong coupling point. One outcome of analyzing a number of examples is that the anomaly polynomial in all cases reveals an RG flow rather than a duality. In fact these get rid of all the potential dualities among $(1,0)$ SCFTs that have distinct weakly coupled tensor branches. In other words, we find evidence that if two $(1,0)$ SCFTs in six dimensions have a different description on their respective tensor branches, then they cannot be equivalent upon moving to the strong coupling point by tuning the vevs of the scalars in the tensor multiplets. In particular this suggests that the classification of reference [20], which in principle only classified 6D theories up to dualities actually contains no redundancies, i.e. there are no non-trivial dualities.

Our plan in this section will be to calculate the anomaly polynomial for a UV SCFT, and study what becomes of this quantity after applying various types of geometric deformations. In particular, we check that when we restrict to the unbroken flavor symmetries common to the UV and IR theories, the difference in the anomaly polynomial is a perfect square, in accord with the general considerations of reference [25].

First, we study examples based on tensor branch flows. We then turn to Higgs branch flows, both for weakly coupled systems as well as Higgsing by activating vevs for conformal matter. Then, we check that the flow from the theory of two small $E_8$ instantons (with tensor branch $[E_8],1,2$) to two single $E_8$ instanton theories (two independent $-1$ curves), is consistent with anomaly matching considerations. We subsequently consider gauging the $E_8$ flavor symmetries of the above two systems, yielding the configurations $12,1,2$ and $1,12,1$, respectively. From the perspective of geometry, these two cases both lead to singular geometries which are connected by higher order deformations. In this case a direct computation of the normalizability of these deformation moduli is quite non-trivial, but the analysis of the anomaly polynomials is again straightforward. Using this method, we establish that there is indeed a flow from the $12,1,2$ theory to the $1,12,1$ theory. This shows that the picture of RG flow is the correct one, and these theories are not dual.

We also consider the detailed examples of reference [20], and the remarkable correspondence between the discrete data of heterotic small instantons probing an ADE singularity and the F-theory realizations of these SCFTs. An important element of this match hinges on correctly identifying the flavor symmetries on the two sides of the correspondence. Following the general prescription outlined in reference [20], there can often be multiple F-theory geometries with the same flavor symmetries. Based on our discussion from the previous sections, it is natural to expect that theories with the same flavor symmetry can actually be organized according to a sequence of flows, as giving a vev to operators parameterizing the Higgs branch is orthogonal to the data which fixes the asymptotic geometry of the instantons. Indeed we find highly non-trivial evidence that $E_8$ instanton theories with fixed bundle data organize themselves into classes uniquely labeled by asymptotic instanton bundle data, the members of which are related to each other by RG flow. The generic theory with no tuned moduli (but the same flavor symmetries) is at the bottom of the flow. It would be interesting to directly verify this picture on the (often strongly coupled) heterotic side.
4.1 Flows on the tensor branch

In this section we consider flows initiated by activating vevs for the scalars in a tensor multiplet, i.e. flows on the tensor branch of the moduli space. Geometrically, this corresponds to resolving some of the $\mathbb{P}^1$'s of the base to finite size. Since all known 6D SCFTs are built out of tree-like structures, we can typically expect to get two or more decoupled SCFTs in the infrared. Our plan will be to compute the anomaly polynomial for the UV theory, and to compare it with the anomaly polynomial of the full infrared theory. As expected from reference [25], we find that when we restrict to the unbroken symmetry currents common to the UV and IR, that the difference anomaly polynomials is a perfect square.

Consider for example a flow from a theory of the rank $k$ E-string theory to a lower rank E-string theory. In the UV theory, the tensor branch is given by $k \mathbb{P}^1$’s intersecting as 1, 2, ..., 2. We can initiate a flow to the infrared by choosing one of these $\mathbb{P}^1$’s, and resolving it to a large size, whilst still keeping the other curves collapsed at zero size. In the heterotic M-theory description, this amounts to pulling some number of M5-branes off the $E_8$ wall.

Our first item of business is therefore to determine the resulting IR theory. First of all, we have the rank $(k - m)$ E-string theory (i.e. the M5-branes still stuck on the wall). The flavor symmetries for this system are the $E_8$ wall of the heterotic nine-brane, and the isometries $SO(4) \simeq (SU(2)_L \times SU(2)_R)/\mathbb{Z}_2$ of the non-compact directions transverse to the M5-branes. We identify $SU(2)_R$ with the R-symmetry of our theory. Turning next to the $m$ M5-branes, we actually find two SCFTs. First, we have the interacting $A_m(2,0)$ theory. Additionally, we have a single $(2,0)$ tensor multiplet which controls the center of mass degrees of freedom of the M5-brane. In terms of $(1,0)$ multiplets, this is a single hypermultiplet (i.e. the relative position of the M5-brane stack compared with the wall), and a $(1,0)$ tensor multiplet, the scalar of which controls the position of the M5-branes from the $E_8$ wall. For the M5-brane theory, the IR symmetry group is $SO(5)_R$, i.e. the directions transverse to the M5-brane, of which the $SO(4)$ isometries are common to both systems.

The case of pulling off a single M5-brane (i.e. $m = 1$) was obtained in [25], and our analysis amounts to a mild generalization of this result. Comparing the differences in the UV and IR anomaly polynomials, and restricting to the unbroken symmetry generators which are common to both systems, we find that the difference is indeed a perfect square:

$$I_{UV} - I_{IR} = \frac{m}{32} \left( \text{Tr} F_{E_8}^2 + (4k - 2m - 2)c_2(L) - (4k - 2m + 2)c_2(R) + p_1(T) \right)^2. \quad (4.1)$$

Here, we have used the general expression for the anomaly polynomial of the E-string theory and the theory of M5-branes, which we reproduce below for the convenience of the reader:

$$I[k \text{ M5's}] = \frac{k^3}{24} (c_2(L) - c_2(R))^2 - k I_8 \quad (4.2)$$

$$I[k \text{ E-strings}] = k^3 \frac{(c_2(L) - c_2(R))^2}{6} + k^2 \frac{(c_2(L) - c_2(R)) I_4}{2} + k \left( \frac{I_2^2}{2} - I_8 \right) \quad (4.3)$$

with notation as in section 3. We note that in the above expressions, the center of mass degrees of freedom have been included. In the case of the tensor branch flow, the fact that
the scalar of the tensor multiplet is neutral under all of the UV flavor symmetries means we can track anomaly matching for all of the terms in the IR as well. When we turn to Higgs branch flows, only a subset of global symmetries will be left unbroken.

As a more involved example, consider the case of M5-branes probing the geometry \( \mathbb{R}_+ \times \mathbb{C}^2 / \Gamma_{ADE} \), where \( \Gamma_{ADE} \) is a discrete ADE subgroup of SU(2). The anomaly polynomial for this system was determined in reference [24], and we can also calculate it using the recursive method explained in that reference and reviewed in section 3. Letting \( G \) denote the corresponding simply connected ADE Lie group associated with the singularity, we see that when we have \( Q \) M5-branes, the UV theory consists of a generalized quiver with \((G,G)\) conformal matter between each link. In the case of \( Q \) M5-branes we have \( Q \) such links, and \((Q-1)\) generalized quiver nodes:

\[
\text{UV Theory: } [G_L] \oplus \underbrace{(2) \oplus \cdots \oplus (2)}_{Q-1} \oplus [G_R].
\] (4.4)

The anomaly polynomial for the UV SCFT is given by [24]:

\[
I[Q, \Gamma] = I[Q \text{ M5}'s at } \mathbb{C}^2 / \Gamma] - I_{\text{tensor}} - \frac{1}{2Q} \left( \frac{1}{4} \text{Tr} F^2_L - \frac{1}{4} \text{Tr} F^2_R \right)^2,
\] (4.5)

where \( \text{Tr} F^2_L \) is associated with the flavor symmetry \( G_L \), with similar notation for \( G_R \). Additionally, the anomaly polynomial for the M5-brane probe theory is [24]:

\[
I[Q \text{ M5}'s at } \mathbb{C}^2 / \Gamma] = \frac{Q^3 |\Gamma|^2}{24} c_2(R)^2 - Q I_8 - \frac{Q|\Gamma|}{2} c_2(R)(J_{4,L} + J_{4,R}) - \frac{1}{2} I^\text{vec}_L - \frac{1}{2} I^\text{vec}_R,
\] (4.6)

where \( J_{4,L} \) and \( J_{4,R} \) are additional contributions from the orbifold singularity itself:

\[
J_{4,L,R} = \frac{\chi_{\Gamma}}{48} (4c_2(R) + p_1(T)) + \text{Tr} F^2_{L,R},
\] (4.7)

with \( \chi_{\Gamma} = r_{\Gamma} + 1 - |\Gamma|^{-1} \), and \( r_{\Gamma} \) the rank of \( G \).

Starting from this UV SCFT, we can initiate a tensor branch flow by sending one of our quiver nodes to weak coupling, i.e. by taking it to have very large size. In the M-theory description, this corresponds to keeping the M5-branes at the singularity, but partitioning them up as \( Q = k + l \) into two separated stacks by moving them apart in the \( \mathbb{R}_+ \) direction. See figure 3 for a depiction of this process for the case two M5-branes at an \( E_8 \) singularity.

The infrared SCFT actually consists of several decoupled SCFTs. First of all, we now have two decoupled generalized quivers. Additionally, we have the volume of the curve we have blown up, and the associated free vector multiplets. Summarizing, here are the IR systems:

\[
\text{IR Theory: } [G_L] \oplus \underbrace{(2) \oplus \cdots \oplus (2)}_{k-1} \oplus [G'_{R}] \sqcup T_{(1,0)} \sqcup V^\oplus_{\text{dc}} \sqcup [G'_{L}] \oplus \underbrace{(2) \oplus \cdots \oplus (2)}_{l-1} \oplus [G_R].
\] (4.8)

where \( V^\oplus_{\text{dc}} \) denotes the \( d_G \) free vector multiplets obtained at zero gauge coupling. Observe that the IR theory has additional flavor symmetries compared with the UV theory. In this
Figure 3. Two M5-branes probing an $E_8$ singularity. A tensor branch flow occurs when the two branes are separated along the singular locus.

case, the F-theory geometry allows us to cleanly track these emergent symmetries. The anomaly polynomial for the IR system is:

$$I_{IR} = I[k, \Gamma] + I[l, \Gamma] + I[T_{(1,0)}] + I[V \oplus d_G].$$  \hspace{1cm} (4.9)

Let us now track the change in the anomaly polynomial for this system. Again, we need to make sure that if we restrict to global symmetries common to both systems that there is an exact factorization. So, we shall keep $\text{Tr} F_{L}^{2}, \text{Tr} F_{R}^{2}$. There is an additional $E_8$ global symmetry in the IR denoting the field strength of the quiver node we have decompactified, but we ignore this symmetry in what follows. For expository purposes we present the result for the case where there is no independent quartic Casimir invariant. This includes all of the exceptional gauge groups as well as $G = SU(2)$ and $G = SU(3)$. The difference in the anomaly polynomials is then:

$$I_{UV} - I_{IR} = \frac{1}{32 klQ} \left( -l \text{Tr} F_{L}^{2} - k \text{Tr} F_{R}^{2} + 2 klQ |\Gamma| c_{2}(R) \right)^{2}$$  \hspace{1cm} (4.10)

which is manifestly a perfect square.

We emphasize that although we have used the M-theory description to guide the reader through the above examples, all of our computations can be phrased purely in terms of the F-theory realization of these SCFTs. As a more involved example along these lines, consider the F-theory model,

$$\begin{align*}
\text{UV Theory: } & [SO(20)]^{sp_3} [SU(2)]^{su_4} \\
\text{IR Theory: } & [Sp(3)]^{su_4} [SU(2)] \sqcup I[T_{(1,0)}] \sqcup V^{\oplus 21} \sqcup H^{\oplus 60}.
\end{align*}$$  \hspace{1cm} (4.11)

The $SO(20)$ flavor symmetry comes from the 10 full hypermultiplets of $sp_3$ living on the $-1$ node, while the $SU(2)$ flavor symmetry comes from the two hypermultiplets of $su_4$ living on the $-2$ curve. We claim this theory flows to four decoupled sectors in the IR,

$$\begin{align*}
\text{IR Theory: } & [Sp(3)]^{su_4} [SU(2)] \sqcup I[T_{(1,0)}] \sqcup V^{\oplus 21} \sqcup H^{\oplus 60}.
\end{align*}$$  \hspace{1cm} (4.12)

Here, the 60 free hypers come from the 10 $6$s of $sp_3$, while the 21 free vectors come from the vector of $sp_3$ in the UV theory. We know that the UV global symmetry $SO(20)$ and the
IR global symmetry $\text{Sp}(3)$ are not preserved along the flow, so if we turn these symmetries off, we find that the difference between the anomaly polynomials is,

\[ I_{\text{UV}} - I_{\text{IR}} = \frac{1}{64}(-48c_2(R) + \text{Tr} F_{\text{SU}(2)}^2 + 2p_1(T))^2. \] (4.13)

This is once again a perfect square! This provides a highly non-trivial check that the conformal sectors of the IR theory are indeed those shown in (4.12).

4.2 Flows on the Higgs branch

We can also consider RG flows initiated by complex structure deformations. At weak coupling, these are interpreted as giving vevs to the scalars of a hypermultiplet, and at strong coupling these are interpreted as giving vevs to conformal matter. In contrast to the case of tensor branch flows, the UV R-symmetry will be broken once we activate such a vev. This means in particular that if we compare the anomaly polynomials in the UV and the IR, there is a priori no reason for the contributions involving $c_2(R)$ to form a perfect square. This is simply because the UV and IR R-symmetries will generically be different. Said differently, this is because the infrared R-symmetry is emergent. If, however, we restrict to symmetries which are preserved along the flow (i.e. present in the UV and the IR), then we should still expect factorization into a perfect square.

As a first class of examples, consider activating vevs for hypermultiplets. In F-theory this corresponds to moving some seven-branes around. In most cases, it is straightforward to identify flows in both physical terms as well as in the F-theory geometry. Examples of this type include the vevs for hypermultiplets of a gauge theory on the tensor branch. For example, in the case of a $-2$ curve with an $I_n$ fiber, we have an $\text{su}_n$ gauge theory coupled to $2n$ flavors. The local presentation is that of a curve of $A_{n+1}$ singularities which has been unfolded to a lower singularity type:

\[ y^2 = x^2 + u^{2n}v^n \rightarrow x^2 + u^n \prod_{i=1}^{n}(uv + t_i), \] (4.14)

where $u = 0$ corresponds to an $\text{SU}(2n)$ flavor symmetry, and $v = 0$ corresponds to our $\text{su}_n$ gauge symmetry.

There are, however, other deformations of our geometry which do not obviously correspond to deformations of the physical theory. Again focussing on the above example, consider moving the marked points where the hypermultiplets are localized. At generic values of the complex structure moduli, we can instead consider the model:

\[ y^2 = x^2 + v^n \prod_{i=1}^{2n}(u - u_i). \] (4.15)

This begs the question: do these moduli correspond to additional deformations of our SCFT? For example, the presence of an $\text{SU}(2n)$ flavor symmetry has now been obscured.

Now, in this special case, these additional moduli do not enter into the SCFT. We can see this by explicitly calculating the anomaly polynomial in the tuned case (all $u_i = 0$) and
the generic case as well. In both cases, we count exactly $2n$ weakly coupled hypermultiplets, so anomaly matching considerations indicate that there is no flow from the tuned case to the generic case. Said differently, these two geometries lead us to the same 6D SCFT.

But in some cases a weakly coupled interpretation is unavailable, as will occur any time we deal with conformal matter. As a simple example, consider Higgsing a single conformal matter sector, say of $(E_8, E_8)$ type (figure 1). In the M-theory picture this corresponds to lifting off the M5-brane from the $E_8$ singularity locus. The theory flows to a theory of an extra hypermultiplet plus the degrees of freedom living on the $E_8$ singularity. The flavor symmetry, which was two copies of $E_8$, is now broken to the diagonal $E_8$. The degrees of freedom living on the $E_8$ singularity are given simply by the reduction from the 7D supersymmetric $E_8$ gauge theory to a theory in 6 dimensions. The vector symmetry is now a global symmetry, but there is also an adjoint hypermultiplet of $E_8$. The anomaly polynomial for this diagonal $E_8$ is,

$$A_{UV} - A_{IR} = A_{[E_8][E_8]} - A_{(248+1)\text{Hyper}} = \frac{4163c_2(R)^2}{8} - \frac{45}{2}c_2(R)\text{Tr}F^2 - \frac{277c_2(R)p_1(T)}{16},$$

(4.16)

Notice that again if we turn off $R$ we get a perfect match between the two anomaly polynomials. Note that the coefficient of $c_2(R)^2$ has decreased, which for tensor branch flows follows from the fact that the difference in the anomaly polynomial is a positive definite quadratic form.

### 4.2.1 Instantons probing an $E_8$ wall

Consider the theory of two heterotic small instantons, which is realized in M-theory by two M5-branes probing an $E_8$ wall, as shown in figure 4. In the F-theory picture, this corresponds to a base of the form

$$[E_8] 1 2$$

(4.17)

Here, the separation of the M5-branes corresponds to the sizes of the two $\mathbb{P}^1$s $t_1$, $t_2$, and the conformal limit is reached by taking the M5-branes to the wall, $t_1, t_2 \to 0$. The $-1$ curve holds an $E_8$ flavor symmetry, corresponding to a non-compact locus of type $II^*$. Starting from this configuration with $t_1, t_2 \to 0$, we next consider separating the M5-branes along a direction parallel to the $E_8$ wall, as shown in figure 5. As the separation along the wall grows large, the theories living on the two M5 branes decouple, and we are left with two decoupled theories of the form

$$[E_8] 1$$

(4.18)

In this manner, we get an RG flow from a rank-2 E-string theory to two decoupled rank-1 E-strings. In the UV theory, our global symmetry is $E_8 \times SU(2)_L \times SU(2)_R$. Now, when we move the instantons apart, there is a hypermultiplet controlling the relative positions of the two instantons. This specifies a vector in $SO(4)$ and as such breaks $SU(2)_L \times SU(2)_R$ to the diagonal subgroup $SU(2)_{\text{diag}}$. In the IR where the two instantons have decoupled, we find that each sector has (in addition to the common R-symmetry) its own $E_8 \times SU(2)_L$
flavor symmetry. In fact, in the special case of the one instanton theory, the $\text{SU(2)}_L$ acts only on the center of mass hypermultiplet of an E-string. This then is a simple example where the infrared R-symmetry is emergent.

The anomaly polynomial for the UV, rank two E-string theory is (including the center of mass degree of freedom):

$$I_{UV} = \frac{31c_2(R)^2}{12} - \frac{3}{4}c_2(R)\text{Tr}F_{E_8}^2 - \frac{17c_2(R)p_1(T)}{24} + \frac{1}{8}p_1(T)\text{Tr}F_{E_8}^2 + \frac{(\text{Tr}F_{E_8}^2)^2}{16}$$

$$+ \frac{7p_1(T)^2}{96} - \frac{p_2(T)}{24}. \quad (4.19)$$

Here, we have dropped the contribution from $c_2(L)$. Indeed, once we initiate a flow to the IR, we break to the diagonal of $\text{SU(2)}_L \times \text{SU(2)}_R$, and we only recover the R-symmetry in the IR. The anomaly polynomial for the IR theory of two rank one E-strings (including
each center of mass degree of freedom) is:

\[ I_{\text{IR}} = \frac{13c_2(R)^2}{12} - \frac{1}{4}c_2(R)\text{Tr}F_{(1)}^2 - \frac{1}{4}c_2(R)\text{Tr}F_{(2)}^2 - \frac{11c_2(R)p_1(T)}{24} + \frac{1}{16}p_1(T)\text{Tr}F_{(1)}^2 \]

\[ + \frac{(\text{Tr}F_{(1)}^2)^2}{32} + \frac{1}{16}p_1(T)\text{Tr}F_{(2)}^2 + \frac{(\text{Tr}F_{(2)}^2)^2}{32} + \frac{7p_1(T)^2}{96} - \frac{p_2(T)}{24} \]  

(4.20)

where again we have dropped the contribution from \( c_2(L) \) from each of our E-string theories (as they are not common to the UV). We have, however, kept the contribution from \( c_2(R) \). Here, we have indicated the two \( E_8 \) flavor symmetries of the IR as \( \text{Tr}F_{(1)}^2 \) and \( \text{Tr}F_{(2)}^2 \). If we consider only the diagonal subgroup by taking \( \text{Tr}F_{(1)}^2, \text{Tr}F_{(2)}^2 \rightarrow \text{Tr}F_{E_8}^2 \) and setting the combination \( \text{Tr}F_{(1)}^2 - \text{Tr}F_{(2)}^2 \) to zero, we find,

\[ I_{\text{UV}} - I_{\text{IR}} = \frac{3c_2(R)^2}{2} - \frac{1}{4}c_2(R)\text{Tr}F_{E_8}^2 - \frac{c_2(R)p_1(T)}{4}. \]

(4.21)

The terms depending solely on the field strength of diagonal \( E_8 \) subgroup have canceled! Thus, we see that the diagonal \( E_8 \) subgroup has been preserved under the flow, whereas the \( SU(2)_R \) symmetry has not. Note again that the coefficient of \( c_2(R)^2 \) has decreased. Finally, we note that if we restrict to the diagonal \( SU(2)_\text{diag} \subset SU(2)_L \times SU(2)_R \) common to both the UV and IR theories, the difference in the anomaly polynomials exactly vanishes.

Next, we consider compactifying the \( E_8 \) locus, resulting in an F-theory geometry with a \(-12\) curve carrying a \( I_1^* \) fiber. Our new UV theory is specified by the base geometry,

\[
\begin{array}{c}
\begin{array}{c}
\mathfrak{e}_8 \\
1212
\end{array}
\end{array}
\]

(4.22)

The IR theory is specified by the geometry,

\[
\begin{array}{c}
\begin{array}{c}
\mathfrak{e}_8 \\
1121
\end{array}
\end{array}
\]

(4.23)

The Weierstrass model is:

|       | Equation                     | Curves       |
|-------|------------------------------|--------------|
| UV    | \( y^2 = x^3 + v^5u^2 + v^6 \) | (12), 1, 2   |
| IR    | \( y^2 = x^3 + v^5(u - u_1)(u - u_2) + v^6 \) | 1, (12), 1   |

(4.24)

In the IR model, the elliptic model becomes too singular at the collision of \( v = 0 \) and \( u = u_i \). This necessitates a blowup in the base, giving us a \(-1\) curve. In the tuned model, multiple blowups are required at the same point, leading us to a model where the entire rank 2 E-string theory touches the \(-12\) curve at a single point.

Based on our example from the previous subsection with weakly coupled hypermultiplets, we might at first suppose that the moduli \( u_i \) correspond to irrelevant deformations of the physical theory. There are various ways to see, however, that the IR model is actually distinct from the UV model. In fact we can view this as gauging an \( E_8 \) flavor symmetry of two theories related by RG flow, which we discussed in the previous example. Therefore this would suggest that the resulting theories should not be equivalent but also related by RG
flow (hence the labels “UV” and “IR”). As this model is quite singular, a direct mathematical analysis of the normalizability of the deformations is rather challenging. In its place, to settle the matter, we can use our analysis of anomaly polynomials to compare the two theories. First of all, we can calculate the difference of the two anomaly polynomials. In the first case, we have a rank 2 E-string coupled to an $\mathfrak{e}_8$ gauge theory. Again, we must properly take into account the contribution from the free hypermultiplet describing the position of the E-string theory on the compact curve. We compare this with the case of two individual E-strings. Here, we have additional free hypermultiplets from moving each of the E-strings to a new point on the $-12$ curve. Comparing the two anomaly polynomials, we have:

$$I_{\text{UV}} - I_{\text{IR}} = \frac{19}{4} c_2(R)^2 - \frac{c_2(R)p_1(T)}{20}.$$  \hspace{1cm} (4.25)

Once again, we see that the terms proportional to $c_2(R)$ have not canceled. This is a good indication that these theories have different degrees of freedom and should be viewed as distinct. Note that again the coefficient of $c_2(R)^2$ has decreased.

Based on this, we conclude that the two theories are in fact distinct and that the deformation moduli we have encountered should be viewed as operator vevs which can move us between theories. Similar considerations hold for an $\mathfrak{e}_8$ gauge theory with rank $k$ E-strings versus one with $k$ rank one E-strings. Indeed, we can then label all the different possible theories according to the ways to partition up $k$ points, i.e. Young tableaux with $k$ boxes.

We may perform a similar analysis for theories specified by F-theory geometries of the form,

$$\mathfrak{g}, 1, 2 \quad \text{vs} \quad 1, \mathfrak{g}, 1$$  \hspace{1cm} (4.26)

For instance, consider

$$\frac{i_2}{5} \begin{array}{c} 1 \\ G_2 \end{array} \quad \text{vs} \quad [G_2] \begin{array}{c} 1 \\ 1, 5, 1 \end{array}$$  \hspace{1cm} (4.27)

As before, we only consider the diagonal subgroup of the flavor symmetry $G_2 \times G_2$, as it is common to both the UV and the IR. We find that the difference between the anomaly polynomials between the left (UV) and right (IR) theories is,

$$I_{\text{UV}} - I_{\text{IR}} = \frac{16c_2(R)^2}{3} - \frac{5}{12} c_2(R)\text{Tr} F_{G_2}^2 - \frac{c_2(R)p_1(T)}{6}.$$  \hspace{1cm} (4.28)

Once again, the terms dependent only on the $G_2$ flavor symmetry have canceled whereas the ones dependent on SU(2)$_R$ have not, indicating that the $R$-symmetry has been broken along the flow while the diagonal $G_2$ flavor symmetry has been preserved.

From the F-theory perspective, this family of flows once again corresponds to separating the two marked points on the central $\mathbb{P}^1$ with gauge group $G$. The points mark the locations of the intersections with the two other $\mathbb{P}^1$s. In the UV, these marked points lie on top of each other, but as we flow to the IR, the marked points are separated.
4.2.2 Instantons on a $\Gamma_{E_8}$ orbifold

We next consider the case of heterotic small instantons probing the orbifold singularity $\mathbb{C}^2/\Gamma_{E_8}$. As explained in [17, 20], these small instanton theories have additional boundary data captured by a choice of homomorphism $\Gamma_{E_8} \to E_8$. We focus on a particularly tractable example where we take the SU(2) subgroup of $(\text{SU}(2) \times E_7)/\mathbb{Z}_2 \subset E_8$. This leads to an unbroken $E_7$ flavor symmetry. Thus, we seek an F-theory model with an $E_7 \times E_8$ flavor symmetry. Here, the $E_7$ factor comes from the unbroken flavor symmetry of the Horava-Witten wall, and the $E_8$ is from the orbifold singularity.

We find that there is actually more than one F-theory geometry with an $E_7 \times E_8$ flavor symmetry. On the tensor branch, these two theories are:

- **UV Model:** $[E_7] \oplus \underbrace{\varepsilon^7 \oplus (11) \oplus (12) \oplus \ldots (12)}_{k} \oplus [E_8] \quad (4.29)$

- **IR Model:** $[E_7] \oplus \underbrace{(11) \oplus (12) \oplus \ldots (12)}_{k} \oplus [E_8]. \quad (4.30)$

Here, we have used the compressed notation of reference [20] to indicate various types of conformal matter:

\begin{align*}
E_7 \oplus E_7 &\simeq E_7, 1, 2, 3, 2, 1, E_7 \\
E_7 \oplus E_8 &\simeq E_7, 1, 2, 3, 1, 5, 1, 3, 2, 2, 1, E_8 \\
E_8 \oplus E_8 &\simeq E_8, 1, 2, 2, 3, 1, 5, 1, 3, 2, 2, 1, E_8. \quad (4.33)
\end{align*}

Our plan in this section will be to perform two computations. First of all, we study the smoothing deformation where we give a vev to the $E_7 \oplus E_7$ conformal matter. This can be interpreted as a standard Higgsing operation whereby we flow to the diagonal $E_7$. Since one of our group factors is a flavor symmetry, the resulting system again has an $E_7$ flavor symmetry, i.e. we flow to the IR model. We shall then explicitly verify that there is indeed a flow by comparing the values of the anomaly polynomials for these two theories.

So, let us begin with the analysis of the smoothing deformations of the singularity. We begin with all curves blown down so that we just see the two flavor branes for the leftmost $[E_7]$ and the rightmost $[E_8]$, which collide along a complicated singularity. Denote the locus of the $E_7$ flavor brane by $\sigma = 0$ and the $E_8$ flavor brane by $\tau = 0$, so that $\sigma^3 \tau^4$ divides $f$ and $\sigma^5 \tau^5$ divides $g$.

The family of singularities that includes both of these types is:

\[ y^2 = x^3 + \alpha \sigma^3 \tau^4 x + (\beta \sigma + \gamma \sigma^2 + \delta \sigma^3) \sigma^5 \tau^5. \quad (4.34) \]

We first blow up the origin, focusing on the chart away from the $E_8$ flavor brane. To do this, we introduce new coordinates $(s, t)$ with $\sigma = st, \tau = t$. Substituting and dividing by the appropriate powers of $t$, we find the new equation:

\[ y^2 = x^3 + \alpha s^3 t^4 + (\beta + \gamma s + \delta t) s^5 t^5. \quad (4.35) \]
For simplicity, we set $\gamma = 1$, giving the equation:

$$y^2 = x^3 + \alpha s^3 t^4 + (\beta + s + \delta t) s^5 t^5.$$  \hfill (4.36)

When $\beta \neq 0$, the additional small instanton is located at the extra zero of $g$ along $t = 0$, that is, at $s = -\beta$, $t = 0$. We blow this up (for arbitrary $\beta$). On the chart away from the $\epsilon_8$ gauge brane, we can describe the blowup by two new coordinates $(u,v)$ satisfying $s = uv - \beta$, $t = v$. Substituting, and dividing by appropriate powers of $v$, we get:

$$y^2 = x^3 + (uv - \beta)^3 x + (u + \delta)(uv - \beta)^5.$$  \hfill (4.37)

We see the $E_7$ flavor brane is at $uv = \beta$ for generic $\beta$. When $\beta = 0$, there are two $E_7$ branes: along the exceptional divisor $v = 0$ we are getting an $\epsilon_7$ gauge brane, while along $u = 0$ we get a (noncompact) $E_7$ flavor brane. The physical interpretation of our parameter $\beta$ is nothing but the vev of the recombination operator for $(E_7, E_7)$ conformal matter [18]. This is a good indication that we have indeed initiated a flow from the UV to the IR.

To provide further evidence for this picture, we next consider the anomaly polynomial for our two theories. Here and henceforth, we restrict our anomaly polynomial computations to the case of a single $\epsilon_8$ gauge algebra, i.e. we consider the specific cases of $(4.29)$ and $(4.30)$ with $k = 1$. The anomaly polynomial takes the form:

$$I_{\text{UV}} = \frac{44297 c_2(R)^2}{2} - 70 c_2(R) \text{Tr} F_L^2 - \frac{237}{4} c_2(R) \text{Tr} F_R^2 - \frac{451 c_2(R) p_1(T)}{4} + \frac{1}{16} \text{Tr} F_L^2 \text{Tr} F_R^2 + \frac{5}{16} p_1(T) \text{Tr} F_L^2 + \frac{3}{8} p_1(T) \text{Tr} F_R^2 + \frac{3(\text{Tr} F_R^2)^2}{16} + \frac{49 p_1(T)^2}{144} - \frac{7 p_2(T)}{36}$$  \hfill (4.38)

Here and in the following equations, $F_L$ is the field strength of the $E_7$ global symmetry on the left of the configuration, while $F_R$ is the field strength of the $E_8$ global symmetry on the right. The anomaly polynomial for the IR theory is,

$$I_{\text{IR}} = \frac{196523 c_2(R)^2}{24} - 40 c_2(R) \text{Tr} F_L^2 - \frac{165}{4} c_2(R) \text{Tr} F_R^2 - \frac{3301 c_2(R) p_1(T)}{48} + \frac{1}{16} \text{Tr} F_L^2 \text{Tr} F_R^2 + \frac{5}{16} p_1(T) \text{Tr} F_L^2 + \frac{3}{8} p_1(T) \text{Tr} F_R^2 + \frac{3(\text{Tr} F_R^2)^2}{16} + \frac{49 p_1(T)^2}{144} - \frac{7 p_2(T)}{36}$$  \hfill (4.39)

The difference is therefore,

$$I_{\text{UV}} - I_{\text{IR}} = c_2(R) \left( \frac{335041 c_2(R)}{24} - 30 \text{Tr} F_L^2 - 18 \text{Tr} F_R^2 - \frac{2111 p_1(T)}{48} \right)$$  \hfill (4.40)

We note that again the difference vanishes when we set $R$ to zero and that again the coefficient of $c_2(R)^2$ has decreased along the flow. This holds true regardless of the number of $-12$ curves in the linear quiver, and the anomaly polynomials of the UV and IR theories in the flows studied in this paper will be equal up to terms proportional to $c_2(R)$.
4.3 Further examples of instanton flows

Similar considerations apply for other flows involving heterotic small instantons probing an orbifold singularity. Again, the picture of flows is most transparent in the language of F-theory on the tensor branch. In this subsection we collect some additional examples of this type, including the relevant flow from UV to IR. For specificity, we again focus on the case where the orbifold singularity is generated by $\Gamma_{E_8}$, the binary octahedral group. In our conventions, the flavor $[E_8]$ is just to the right of the first gauge $e_8$ curve and contracting the curves in between the $e_8/E_8$ conformal matter leads to five blowdowns on the gauged $e_8$ curve. We also blow up small instantons on that $e_8$ curve. To keep our presentation somewhat compact, we use the $\oplus$ notation to denote the curves generated by performing a minimal number of blowups between two other gauge groups. Note that this slightly generalizes the notion of “links” to the case where one of the gauge group factors is not simply laced. Also, we note that there are well over one hundred different small instanton probe theories which can be related by various flows. Our aim here is therefore simply to select a few examples which illustrate the general ideas presented earlier. For each of these flows, we may calculate the change in matter charged under the (left, right) flavor symmetries between the UV and IR theories (but uncharged under any gauge symmetries) by comparing the relevant terms in the anomaly polynomial. In particular we find that the analog of an extra hypermultiplet that we got in the IR in previous examples, sometimes involves more non-trivial matter representation of the flavor symmetry. To bring this out, below when we mention $I_{IR}$ we mean the “naïve” IR anomaly polynomial, which does not take into account this additional contribution from matter charged only under the global symmetries. This difference in gauge-neutral matter appears in the tables below as $\varphi_{UV} - \varphi_{IR}$.

What follows is thus a small set of example flows which retain the same flavor symmetry. In all of these examples, we let $F_L$ denote the field strength of the global symmetry on the left of the configuration, while $F_R$ is the field strength of the $E_8$ global symmetry on the right of the configuration. Let us note that in accord with the classification results found in reference [20], there can sometimes be more than one UV theory with the same left global symmetry. This is because there are different group embeddings $\Gamma_{E_8} \to E_8$.

- $E_7 \times E_8$ flavor symmetry

| Flow:          | $[E_7] \oplus 8 \oplus (12) \ldots [E_8] \to [E_7] \oplus (11) \ldots [E_8]$ |
|----------------|----------------------------------------------------------------------------------|
| $I_{UV} - I_{IR}$ | $\frac{335041c_2(R)}{24} - 30c_2(R)\text{Tr}F_L^2 - 18c_2(R)\text{Tr}F_R^2 - \frac{2111c_2(R)p_1(T)}{48} + \frac{7p_1(T)^2}{5760} - \frac{p_2(T)}{1440}$ |
| $\varphi_{UV} - \varphi_{IR}$ | $1 \times (1,1)$ |

(4.41)

- $F_4 \times E_8$ flavor symmetry

\footnote{These contributions can be added back in to the anomaly polynomial by observing that there is no change in the coefficient of the $p_2(T)$ term in flowing from the UV to the IR.}
SU(4) × SU(2) flavor symmetry:

This is another case with a single flow:

| Flow: $\{[F_4] \oplus 8 \oplus (12) \ldots [E_8] \rightarrow [F_4] \oplus (10) \ldots [E_8]$ |
|---|
| $\mathcal{I}_{UV} - \mathcal{I}_{IR}$ |
| $- \frac{394637 c_2(R)^2}{24} + \frac{165}{4} c_2(R) \text{Tr} F_L^2 + 24 c_2(R) \text{Tr} F_R^2 + \frac{2827 c_2(R) p_1(T)}{48}$ |
| $- \frac{1}{16} p_1(T) \text{Tr} F_L^2 - \frac{203 p_1(T)^2}{5760} + \frac{29 p_2(T)}{1440}$ |
| $\varphi_{UV} - \varphi_{IR}$ |
| $1 \times (26,1) + 3 \times (1,1)$ |

(4.42)

The change in the anomaly polynomial is:

(4.43)

The change in the anomaly polynomial is:

$$
\mathcal{I}_{UV} - \mathcal{I}_{IR} = \frac{354121 c_2(R)^2}{24} - \frac{149}{4} c_2(R) \text{Tr} F_L^2 - \frac{165}{4} c_2(R) \text{Tr} F_R^2 - \frac{45}{2} c_2(R) \text{Tr} F_L^2 - \frac{5}{6} p_1(T) \text{Tr} F_L^2
$$

(4.44)

Here, $F_L$ is the field strength for the SU(4) global symmetry, while $F_T$ is the field strength for the SU(2) global symmetry.

For this flow, the global SU(4) and SU(2) flavor symmetries are preserved, and we may calculate the change in matter between the UV and IR theories charged under the SU(4) × SU(2) × $E_8$ global symmetries. The result is

$$
\varphi_{UV} - \varphi_{IR} = 1 \times (4,2,1) + 1 \times (6,1,1) + 1 \times (4,1,1) + \frac{3}{2} \times (1,2,1) + 2 \times (1,1,1)
$$

(4.45)

Recall that $(6,1,1)$ is the antisymmetric representation of SU(4), and $(4,2,1)$ is the bifundamental of $SU(4) \times SU(2)$.

SU(6) × $E_8$ flavor symmetry:

In this case, it turns out that there is a sequence of flows we can do. The main point is that we can also take non-minimal conformal matter, and this sometimes comes with a flavor symmetry. So, taking this into account, we can move around the associated additional E-string from a tuned point to a generic point (i.e. the maneuver of moving marked points). Then, we can also activate a vev for conformal matter, triggering a further flow. We list the UV theory, the intermediate theory, and the IR theory:

| UV Theory | $[SU(6)]_{2} 2 \ 1 8 \oplus (12) \ldots [E_8]$ |
|---|
| Intermediate | $[SU(6)]_{2} 1 6 \oplus (12) \ldots [E_8]$ |
| IR Theory | $[SU(6)]_{2} 1 5 1 3 2 2 1 (11) \ldots [E_8]$ |

(4.46)
The change in the anomaly polynomial is:

\[
I_{\text{UV}} - I_{\text{Intermediate}} = 5574 c_2(R)^2 - 12 c_2(R) \text{Tr} F_L^2 + \frac{1}{96} \text{Tr} F_L^4 - 6 c_2(R) \text{Tr} F_R^2
- \frac{33 c_2(R) p_1(T)}{2} + \frac{1}{96} p_1(T) \text{Tr} F_L^2 + \frac{7 p_1(T)^2}{960} - \frac{p_2(T)}{240}
\]

(4.47)

\[
I_{\text{Intermediate}} - I_{\text{IR}} = \frac{189745 c_2(R)^2}{24} - 18 c_2(R) \text{Tr} F_L^2 - 12 c_2(R) \text{Tr} F_R^2
- \frac{1319 c_2(R) p_1(T)}{48} + \frac{7 p_1(T)^2}{5760} - \frac{p_2(T)}{1440}
\]

(4.48)

The difference in gauge-neutral hypermultiplet content between the UV and intermediate theories can be read off from the anomaly polynomials: the UV theory has an extra fundamental of the SU(6) flavor symmetry relative to the intermediate theory, while the intermediate theory has an extra neutral hyper relative to the IR theory.

5 Conclusions and future directions

Renormalization group flows from the UV to the IR are quite important in the study of quantum field theories. In this paper we have taken some steps in establishing the structure of RG flows for 6D SCFTs which can be realized by F-theory compactification. By combining an analysis of the change in the anomaly polynomial with the deformation theory of the corresponding background Calabi-Yau threefold, we have determined the structure of such flows. Let us briefly discuss some further avenues of investigation.

The examples we have focussed on involve deformations which involve operator vevs for 6D conformal matter. Using the geometric picture, we have seen (as expected) that this conformal matter acts very much like a conventional hypermultiplet. On the other hand, we have also observed some differences. For example, moving the marked points where conformal matter is localized can trigger a flow, which is different from the case of conventional matter. It would be quite interesting to develop further details of this structure, and the corresponding flows.

In this note our primary emphasis was on giving examples of the kinds of phenomena one can expect to encounter in the study of 6D flows. Given the fact that there is also a concrete classification of 6D SCFTs generated by F-theory available, it would be natural to map out all possible flows between these theories.

Finally, our analysis here has focused on general questions connected with RG flow. There is also a holographic interpretation of RG flow. It would be interesting to consider those 6D SCFTs with a holographic dual and determine the detailed structure of such flows and how they interpolate between different gravity duals.
