Aim. To study the long-term effect of renal denervation (RDN) on left ventricular mass (LVM) and inflammatory markers in resistant hypertensive patients.

Material and methods. Forty-one patients with resistant hypertension and 24-h blood pressure (BP) 158.7±15.8/87.3±14.6 mmHg, aged 56.6±10.2 years, were enrolled in the study and undergone RDN. Mean 24-h BP, left ventricular mass (transthoracic echocardiography), high sensitivity C-reactive protein (hsCRP), interleukin-1β (IL-1β), IL-6, IL-10 and tumor necrosis factor alpha (TNF-α) were assessed at baseline and 2 years after the RDN.

Results. A baseline prevalence of left ventricular hypertrophy (LVH) was 90.2%. Two years after RDN LVM and interventricular septum (IVS) decreased significantly (p<0.05 for both). Decrease in myocardial mass (∆LVM >0 g) was documented in 24 patients. The regression of LVM was accompanied by a significant decrease in levels of inflammatory markers — hsCRP by 38.3% (p=0.001), TNF-α by 60.7% (p=0.009), IL-1β by 71.1% (p=0.001), and IL-10 by 58.2% (p=0.001). In patients in the absence of LVM regression only TNF-α decreased significantly (-68.8%; p=0.001). There was no correlation between changes of LVM and the inflammatory markers at 24 months after RDN.

Conclusion. The RDN in RH patients may have long-term cardioprotective effect in terms of significant regress of LVH, which may be partly attributed to the regress in systemic or myocardial inflammation.

Keywords: resistant hypertension, cardioprotective efficacy, left ventricular hypertrophy, renal denervation, inflammation.

Relationships and Activities: none.

Trial ID: NCT 02667912.

Цель. Изучить долгосрочные эффекты ренальной денервации (РД) на массу левого желудочка (МЛЖ) и маркеры воспаления у пациентов с резистентной артериальной гипертензией (АГ).

Материал и методы. В исследование было включено 41 пациент с резистентной АГ (среднее артериальное давление (АД) 158,7±15,8/87,3±14,6 мм рт.ст.) в возрасте 56±10,2 лет, которым была проведена РД. Среднесуточное АД, масса левого желудочка (трансторакальная эхокардиография), высокочувствительный С-реактивный белок (И-СРБ), интерлейкин-1β (ИЛ-1β), ИЛ-6, ИЛ-10 и фактор некроза опухоли альфа (ФНО-α) оценивались на исходном уровне и через 2 года после РД.

Результаты. Исходная частота гипертрофии левого желудочка (ГЛЖ) составляла 90,2%. Через два года после РД, МЛЖ и межжелудочковая перегородка (МЖП) значительно снизились (р<0,05 для обоих показателей). Уменьшение массы миокарда (∆МЛЖ>0 г) было зарегистрировано у 24 пациентов. Уменьшение МЛЖ сопровождалось статистически значимым снижением уровней воспалительных маркеров — И-СРБ на 38,3% (р=0,031), ФНО-α на 60,7% (р=0,009), ИЛ-1β на 71,1% (р=0,001), ИЛ-10 на 58,2% (р=0,001). У пациентов, у которых не наблюдалось снижение МЛЖ, только ФНО-α значительно снизился (-68,8%, р=0,001). Корреляции между изменениями МЛЖ и воспалительными маркераами через 24 месяца после РД выявлено не было.

Заключение. РД у пациентов с резистентной АГ может оказывать долгосрочное кардиопротекторное влияние в виде снижения МЛЖ, что частично может быть связано с уменьшением выраженности системного или миокардального воспаления.

Ключевые слова: резистентная артериальная гипертензия, кардиопротективный эффект, гипертрофия левого желудочка, ренальная денервация, воспаление.

Окончание и др.: нет.

Introduction

Despite the progress in the development of antihypertensive pharmacotherapy a prevalence of uncontrolled arterial hypertension (AH) is still very high. Major classes of antihypertensive drugs can reduce blood pressure (BP), on average, by -9.1/-5.5 mm Hg when administered as monotherapy and around -30/-15 mm Hg when 3 drugs are used in combination [1]. It is obviously not enough for effective treatment of severe AH with BP higher than 180 mm Hg. Therefore, a significant proportion of treated hypertensives remain uncontrolled or treatment-resistant. The risk of stroke and myocardial infarction in patients with resistant hypertension (RH) is twice as high as in those with controlled hypertension.

According to meta-analysis of cross-sectional and longitudinal studies including 3325 patients, left ventricular hypertrophy (LVH) is diagnosed in 55-75% of patients with RH [2]. A negative effect of LVH on clinical course and the outcomes of myocardial infarction has been shown in a large observational study [3]. Also, LVH negatively affected the infarct size in experimental research [4]. The LVH is independent predictor of systolic dysfunction [5]. sudden cardiac death and cardiovascular death. Reduction of LVH or left atrium size due to antihypertensive pharmacotherapy can have a positive effect on a risk of major cardiovascular events [6].

A role of inflammation in the development of AH and hypertensive organ damage has been widely discussed in recent decades. A variety of pro-inflammatory and inflammatory markers have been studied for their relationship with the progression of the disease, especially, high sensitivity C-reactive protein (hsCRP), interleukins and tumor necrosis factors.

One of the most promising therapeutic developments potentially capable to solve the problem of RH is catheter based renal denervation (RDN). Treatment of RH with RDN demonstrates regress of LVH, but with low predictability, and even in the absence of BP response. Also, long-term effects of RDN on LVH are not well studied.

Aim of the study is to determine the long-term effect of RDN on left ventricular mass (LVM) and inflammatory markers in patients with resistant hypertension.

Material and methods

We performed a retrospective analysis of the data from the single center study of RDN in RH patients conducted in the Cardiology Research Institute of Tomsk National Medical Research Center.

Study inclusion criteria were: hypertensive patients of both genders, 18-80 years old, office BP >160/90 mmHg (systolic /diastolic, respectively) despite treatment with maximum tolerated doses of 3 antihypertensive drugs in, one of which was a diuretic. All patients provided written informed consent before inclusion in the study. The patients were excluded if they had secondary hypertension, 24-h mean systolic blood pressure (SBP) <135 mm Hg, glomerular filtration rate (by MDRD formula) (eGFR) <30 mL/min/1.73 m², pregnancy, extended disease of the renal arteries, severe comorbidity significantly increasing risk of the intervention.
The patients meeting eligibility criteria underwent RDN procedure and were followed up for a period up to 3 years.

There were 6-, 12-, 24- and 36-months follow-up examination to assess the effectiveness and safety of renal denervation. The results of the annual observation were presented earlier. This study presents research data from 41 RH patients completed 2 year follow up. Baseline characteristics of the patients and structure of antihypertensive pharmacotherapy are summarized in the table 1.

Results

Two years after RDN the 24-hour BP was significantly decreased compared to baseline (-13.1/-7.4 mm Hg SBP/DBP respectively, p<0.001 for both). The analysis of patient-reported data on the antihypertensive drug use has shown no significant changes in concomitant drug therapy throughout the follow-up (4.14±0.89 vs 4.37±0.93, p<0.16) (table 2).

The baseline prevalence of LVH in the study sample was 90.2%. Two years after RDN LVM was decreased...
2. Cuspidi C, Vaccarella A, Negri F, et al. Resistant hypertension and RDN. There were no serious adverse events associated with the inflammatory markers at 24 months after RDN.

-17.3/-8.5 mm Hg respectively (p<0.01 for both).

-68.8%, p=0.001) (table 4). In a both cases (with and without regress of LVH) BP decreased significantly at two years after RDN 24-h (-8.5/-5.8 and -17.3/-8.5 mm Hg respectively (p<0.01 for both).

There was no correlation between changes of LVM and inflammatory markers at 24 months after RDN. There were no serious adverse events associated with the RDN.

Discussion

RDN as a method of endovascular treatment of RH demonstrates cardioprotective effects but the magnitude of the effects is highly variable. Previous studies of cardioprotective efficacy of RDN were conducted in small patient groups and had a short duration, mainly, up to one year. The regression of LVM and atrial size after RDN was confirmed in metaanalysis of 12 studies with twelve months follow up including 382 patients in total [7]. There was no relationship between cardiac changes and BP reduction after RDN in these studies. Regress of LVM and reduction of the volume of subendocardial damage assessed by contrast enhanced MRI were demonstrated in 35 RH patients over 1 year follow-up after RDN in our center [8]. Currently there are only a few publications on the long-term cardioprotective efficacy of RDN. The study in 18 patients with RH has shown a definite 24-month cardioprotective effect of RDN: regression of LVH was detected in 70.6% cases, the prevalence of concentric remodeling dropped by 47.1%. Cardiac changes were not related to the BP lowering after RDN [9].

The relationship between inflammation and hypertension has been shown in a number of studies [10]. Levels of IL-1β, IL-6, TNF-α in hypertensive patients are significantly higher compared to normotensives [11]. In particular, it has been shown that hsCRP known as a marker of vascular inflammation and remodeling is also involved in the development of LVH [12], has strong association with hypertension [13] and predicts cardiovascular complications in hypertensive patients.

The experimental studies demonstrated that mechanisms of the LVH regression after RDN are not limited to the decrease in sympathetic activity and blood pressure. The levels of expression of myocardial TNF, IL-6, TLR-4 may also be relevant in this regard. An experimental study of RDN performed in spontaneously hypertensive rats has shown that compared to the control Wistar Kyoto spontaneously hypertensive rats had markedly higher blood pressure, LVM and protein expression of TLR4, NF-κB, TNF-α and IL-6 in the myocardium, which were significantly reduced after RDN in contrast with sham-operated animals [14].

In 2015 a group of German authors published a study that documented a significant decrease in IL-6 and CRP whereas an increase in matrix metalloproteinases (MMP-2, MMP-9) at 6 months after RDN [15].

The main finding of our study is that the IVS thickness and LVM assessed by echocardiography decreased significantly at 24 months after RDN. Thus, the RDN in RH patients may have long-term cardioprotective effect, which at least in part may be attributed to the regress in systemic or myocardial inflammatory activity. In spite of the research limitations (small sample, absence of control group) the results obtained are scientific interest and demand continuing the research.

Relationships and Activities: none.
