(Dated: November 3, 2010)

In this work, the effects of quantum interference and spontaneously generated coherence (SGC) are theoretically analyzed in a four level system of a $^{87}$Rb atom. For the effects of SGC, we find that a new kind of EIT channel can be induced due to destructive interference, and the nonlinear Kerr absorption can be coherently narrowed or eliminated under different strengths of the coupling and switching fields.

I. INTRODUCTION

The quantum interference and coherence play the central role in the fields of nonlinear optics, quantum information processing, and quantum wells/dots etc. In recent years, the processes of electromagnetically induced transparency (EIT) \cite{1,2} are widely studied in various systems. Many processes based on EIT, for example, the electromagnetically induced absorption (EIA) \cite{6}, the EIT based four-wave and six-wave mixing \cite{7}, the EIT for X-rays \cite{8}, and the EIT on a single artificial atom \cite{9} are studied. Also, the giant Kerr effect (GKE) \cite{10,11,26} is the natural application of EIT by introducing the switching (signal) field, which has many applications, e.g., in the photonic Mott insulator \cite{23} and the circuit quantum electrodynamics \cite{24} etc. Physically, once the dark state within the EIT is destroyed by the disturbance of the switching field, the EIT disappears, the nonlinear susceptibility and absorptive photon switching occur. The processes of EIT and GKE could be changeable by turning the switching field on and off, and the photon process within can be managed. Recently, the effects of spontaneously generated coherence (SGC) (or termed as vacuum-induced coherence (VIC)) stimulate one’s interests. For instance, in three-level systems the nonlinear Kerr absorptions are shown to be greatly enhanced via SGC \cite{12}. For four-level system, the effects of SGC are studied in the $N$-type system \cite{20} on the nonlinear Kerr absorption, and in double $\Lambda$-type system on the coherent population transfer \cite{25,26}.

Experimentally, it is effective to simulate the effects of SGC by changing the property of the vacuum \cite{27,28}, and/or extra driving fields, such as a dc field \cite{29,31}, a microwave field \cite{32}, or a laser field \cite{33,34} etc. Some experimental groups have realized part effects of SGC in the $V$-type, four-level $\Lambda$-type, and other systems recently \cite{33,37}.

In the present work we study the effects of SGC in EIT and GKE in the four-level of $N$-type and double $\Lambda$-type systems based on the generating function approach developed recently \cite{38,39}. In the double $\Lambda$-type system, SGC can cause new EIT channels due to destructive interference, which could be termed as “vacuum-assisted transparency” (VAT). The usual EIT requires that the detunings of the coupling and probe fields satisfy the two-photon resonance condition. With the effects of SGC, however, transparency can be obtained beyond the two-photon process. This means that we can get the transparency window within the whole detuning range of the probe field. For the nonlinear Kerr absorption in the $N$-type system, the spectra can be narrowed or eliminated with the effect of SGC, under different strengths of the coupling field $\Omega_c$ and switching field $\Omega_s$. We demonstrate that the destroyed dark state can be repaired via SGC under some conditions. Also, we investigate the photon switching process via photon statistics, the variance of the photon distribution can be presented by Mandel’s $Q$ parameter. One of the important case is $Q < 0$, which shows anti-bunching when photon switching occurs.

For the four-level systems in this work, we demonstrate that SGC plays different roles in the linear and nonlinear absorption. By introducing SGC, the ability of the original EIT and GKE can be improved, also the photon statistics can be greatly affected and reflect the characters of different dynamics. The reasons we investigate two type systems together are as follows. Firstly, the two systems are, actually, the same with each other. They have the same structures, and a $^{87}$Rb atom can be their concrete system. Secondly, the $N$-type and double $\Lambda$-type systems are apparent type, their difference comes from the numbers of driving laser fields.

SGC (VIC) shows us another pathway of quantum interference, which serves to mediate the relative contribution of the dipole transitions, and represents the directly coupling between the coherence of the system. SGC (VIC), represented by the generalized decay constants (GDCs), can lead to some novel features in dynamics of atomic systems, and it is shown that SGC plays the important role in many phenomenons \cite{27,30,50,51}, such as the dark state resonance \cite{52,53}, coherent population trapping and transfer \cite{54,57}, spectral narrowing
and elimination [58–60], gain without population inversion [61], spectrum squeezing [62–64] etc.

This paper is organized as follows. In Section III we give our theoretical framework of the quantum dynamics of four-level system of an $^{87}$Rb atom. In our theoretical framework, we include the generalized decay constants (GDCs) within the rotating wave approximation (RWA). In Section III we present our theoretical results of the effect of SGC. In Section IV we give brief conclusion and discussion.

II. THEORETICAL FRAMEWORK

In this work we theoretically study the quantum dynamics of a four-level quantum system driven by external laser fields. The four-level systems are shown in Fig. 1.

In our study, we consider the transition dipole moments: $|3\rangle \rightarrow |1\rangle$, $|3\rangle \rightarrow |2\rangle$, $|4\rangle \rightarrow |1\rangle$, and $|4\rangle \rightarrow |2\rangle$. However, the direct transitions between the states $|2\rangle$ and $|1\rangle$, and $|4\rangle$ and $|3\rangle$ are dipole forbidden. We consider the evolution of the reduced density matrix of the system $\sigma(t) \equiv \text{Tr}_R \{\rho(t)\}$. The evolution of the reduced density matrix satisfies the Liouville equation [65–68]

$$\dot{\sigma}_{ij}(t) = \mathcal{L}_{ij,kl} \sigma_{kl}, \quad (1)$$

where $\mathcal{L}_{ij,kl}$ is the Liouville super-operator. We study the effects of SGC on linear and nonlinear absorptions and also on the photon statistics. One of the convenient approach to calculate photon counting moments is generating function approach developed recently [38–49]. The generating function is defined as [38–49]

$$G(s, t) = \sum_{n=0}^{\infty} \sigma^{(n)}(t)s^n, \quad (2)$$

where $s$ is called the counting variable, $\sigma^{(n)}(t)$ describes the probability that $n$ photons have been emitted in the time interval $[0, t]$, and

$$\sigma(t) = \sum_{n=0}^{\infty} \sigma^{(n)}(t). \quad (3)$$

Similar with Refs. [38–49], the evolution of the generating function of four-level system can, under the rotating wave approximation (RWA), be formally written as

$$\dot{G}_{ij}(s, t) = -i\omega_{ij}G_{ij} - i/2 \sum_{m} (\Omega_{mj}G_{im} - \Omega_{im}G_{mj})$$

$$+ 2s \sum_{k>i, l>j} \gamma_{kijl}G_{kl} - \sum_{k>m} \gamma_{imnk}G_{kj} - \sum_{l>n} \gamma_{lmnj}G_{il}, \quad (4)$$

where the energy spacing $\omega_{ij} = \omega_i - \omega_j$, the Rabi frequency $\Omega_{ij}(t) = ij \cdot \mathcal{E}(t)/\hbar$, $\mathcal{E}(t)$ is the polarization of the field with frequency $\omega_L$, the GDCs are $\gamma_{ijkl} = \mu_{ij} \cdot \mu_{kl} |\omega_{kl}|^3$, where $\omega_{kl} \approx \omega_{ij}$ has been taken into account. $k > i$ represents that the level $|k\rangle$ sits above the level $|i\rangle$. Eq. (4) for the double $\Lambda$-type system and $N$-type system considered in this work is explicitly presented in the following section.

In our study, the GDCs $\gamma_{ijkl}$ can be expressed as [25, 31, 61, 64]

$$\gamma_{kisl} = \beta \sqrt{\gamma_{kis} \gamma_{il}}, \quad (5)$$

the parameter $\beta$ could be named as the “SGC factor”, it takes $0 \leq \beta \leq 1$. When the dipole moments are perpendicular $\beta = 0$, and $\beta = 1$ for the dipole moments parallel case.

In order to extract the information of photon emission events, we define the working generating function

$$\gamma(s, t) = \sum_{k=1}^{4} G_{kk}(s, t). \quad (6)$$

The factorial moments $\langle N^{(m)}(t) \rangle$ and emission probability of $n$ photon $P_n(t)$ can be obtained via [38–49]

$$\langle N^{(m)}(t) \rangle = \langle N(N - 1)(N - 2) \cdots (N - m + 1) \rangle_{(t)}$$

$$= \frac{\partial^m}{\partial s^m} \gamma(s, t)|_{s=1}, \quad (7)$$

and

$$P_n(t) = \frac{1}{n!} \left. \frac{\partial^n}{\partial s^n} \gamma(s, t) \right|_{s=0}. \quad (8)$$

Correspondingly, the absorption line shapes and Mandel’s $Q$ parameter can be obtained

$$I(\omega_L) = \frac{d}{dt} \langle N^{(1)}(t) \rangle_{t=\infty}, \quad (9)$$

$$Q(\omega_L) = \frac{\langle N^{(2)} \rangle - \langle N^{(1)} \rangle^2}{\langle N^{(1)} \rangle}. \quad (10)$$
III. NUMERICAL RESULTS

In this section, we study the effects of SGC on electromagnetically induced transparency and nonlinear Kerr absorption, and on the photon statistics. In our numerical results, we plot absorption line shapes and Mandel’s Q parameter. The absorption is monitored via fluorescence of spontaneously emitted photons. The reason is that the correspondence between photon emission and absorption is insured by conservation of energy \[42, 44\]. Our results can be measured experimentally based on an \(87\)Rb atom. For the convenient of future experiment, all the parameters used in our numerical results are the parameters of the \(87\)Rb atom, the proposed \(D\)-line energy levels of the \(87\)Rb atom in this work are also marked in Fig. 1. In the following equations of generating function \[12, 13\], for convenience, we use the shorthand

\[
\begin{align*}
\gamma_{31} & \equiv \gamma_{3113}, \quad \gamma_{32} \equiv \gamma_{3223}, \\
\gamma_{31} & \equiv \gamma_{3114}, \quad \gamma_{32} \equiv \gamma_{3224}, \\
\Gamma_3 & \equiv \gamma_{3113} + \gamma_{3223}, \\
\Gamma_4 & \equiv \gamma_{3114} + \gamma_{3224}, \\
\Gamma_{34} & \equiv \gamma_{3114} + \gamma_{3224}.
\end{align*}
\]

(11)

It should be noted that we normalize the absorption line shapes in the following sections.

A. DOUBLE \(\Lambda\)-TYPE SYSTEM

In this subsection, we study the process of EIT in the double \(\Lambda\)-type system. Its schematic diagram is shown in panel (a) of Fig. 1. In our numerical results, we refer to the parameters of the \(87\)Rb atom, namely, we set \([5^2S_{1/2}, F = 1] = |1\rangle, \ [5^2S_{1/2}, F = 2] = |2\rangle, \ [5^2P_{1/2}, F' = 1] = |3\rangle, \ [5^2P_{1/2}, F' = 2] = |4\rangle\). The parameters are listed in the caption of Fig. 2.

In this system, the transitions of \(|3\rangle \rightarrow |1\rangle\) and \(|4\rangle \rightarrow |2\rangle\) are probed by the weak probe field, the transitions of \(|3\rangle \rightarrow |2\rangle\) and \(|4\rangle \rightarrow |1\rangle\) are coupled by the strong coupling field. The Rabi frequencies are defined as \(\Omega_{13} = \Omega_{14} = \Omega_p, \ \Omega_{23} = \Omega_{24} = \Omega_c\). The detunings are defined as \(\Delta_p = \omega_p - \omega_{31}, \ \Delta_c = \omega_c - \omega_{32}\), and the separation of the excited states \(\omega = \omega_2 - \omega_3\). The generating function of Eq. (11) for the double \(\Lambda\)-type system is obviously expressed as

\[
\begin{align*}
\dot{G}_{11} &= 2s(\gamma_{31}G_{33} + \gamma_{314}G_{34} + \gamma_{314}G_{43} + \gamma_{41}G_{44} - \frac{i}{2}\Omega_p(G_{13} + G_{14} - G_{31} - G_{41})), \\
\dot{G}_{22} &= 2(\gamma_{32}G_{33} + \gamma_{324}G_{34} + \gamma_{324}G_{43} + \gamma_{42}G_{44} - \frac{i}{2}\Omega_c(G_{23} + G_{24} - G_{32} - G_{42})), \\
\dot{G}_{33} &= -2\Gamma_3G_{33} - \Gamma_4(G_{34} + G_{43}) - \frac{i}{2}\Omega_p(G_{31} - G_{13}) - \frac{i}{2}\Omega_c(G_{32} - G_{23}), \\
\dot{G}_{34} &= -2\Gamma_4G_{44} - \Gamma_4(G_{34} + G_{43}) - \frac{i}{2}\Omega_p(G_{41} - G_{14}) - \frac{i}{2}\Omega_c(G_{42} - G_{24}), \\
\dot{G}_{12} &= -i(\Delta_p - \Delta_c)G_{12} - \frac{i}{2}\Omega_c(G_{13} + G_{14}) + \frac{i}{2}\Omega_p(G_{32} + G_{42}), \\
\dot{G}_{13} &= -i\Delta_pG_{13} - \Gamma_3G_{13} - \Gamma_4G_{14} - \frac{i}{2}\Omega_p(G_{11} - G_{33} - G_{43}) - \frac{i}{2}\Omega_cG_{12}, \\
\dot{G}_{14} &= -i(\Delta_p - \omega)G_{14} - \Gamma_4G_{14} - \Gamma_4G_{11} - \Gamma_4G_{14} - \frac{i}{2}\Omega_p(G_{11} - G_{34} - G_{44}) - \frac{i}{2}\Omega_cG_{12}, \\
\dot{G}_{23} &= -i\Delta_cG_{23} - \Gamma_3G_{23} - \Gamma_4G_{24} - \frac{i}{2}\Omega_c(G_{22} - G_{33} - G_{43}) - \frac{i}{2}\Omega_pG_{21}, \\
\dot{G}_{24} &= -i(\Delta_c - \omega)G_{24} - \Gamma_4G_{24} - \Gamma_4G_{21} - \Gamma_4G_{24} - \frac{i}{2}\Omega_c(G_{22} - G_{34} - G_{44}) - \frac{i}{2}\Omega_pG_{21}, \\
\dot{G}_{34} &= i\omega G_{34} - \Gamma_4G_{34} + G_{34} - (\Gamma_4 + \Gamma_4)G_{34} - \frac{i}{2}\Omega_p(G_{31} - G_{14}) - \frac{i}{2}\Omega_c(G_{32} - G_{24}), \\
\end{align*}
\]

(12)

and the elements not included in Eq. (12) can be obtained by using the complex conjugate relation: \(G_{ij} = G_{ji}^\ast\).

The EIT process in the detuning space \(\Delta_p - \Delta_c\) is shown in Fig. 2. Panels (a) and (b) are the results of the SGC factor \(\beta = 0\), and panels (c) and (d) are the results of \(\beta = 1\). Panels (a) and (c) are absorption line shapes, and panels (b) and (d) are Mandel’s \(Q_p\) parameters.

When \(\beta = 0\), there is no effect of SGC. The absorption line shapes \(I_p\) of the probe field is shown in Fig. 2 (a). It can be seen the transparency signal is on the diagonal.
destructive interference between states are equally excited. The dark state is induced as the similar processes are studied experimentally in the atoms system \[33\] for particular coupling detunings $\Delta$. induced in this system. Particularly, when $|\Delta| > 0$ can cause destructive interference between the transitions absorption line shapes. Physically, the GDCs $\gamma$ are in the units of $\Delta$. The process for $\Delta_p = 0$ is different since the usual EIT channel is induced. The population is almost trapped in the initial ground state $(1)$ in our calculation. The difference between the processes of EIT and VAT means that we can control the population transfer \[37\] by turning the detuning of the coupling field $\Delta_c$. This process of population trapping is similar with the studies in Refs. \[29, 30, 55\]. In the four-level system in Refs. \[29, 30, 55\], two close-lying excited states couple to another auxiliary state by a driving field, and decay to the single ground state. In our system, the difference is that the coupling field and probe field can perform the EIT channel, we can combine the effects of EIT and SGC together, and switch between EIT ($\beta = 0$) and VAT ($\beta \neq 0$). In addition, if the coupling field is turned off, there will be no transparency even though SGC exists. That is to say, the coupling field is necessary to induce the VAT channel.

The characters of $Q_p$ parameter are plotted in panels (b) and (d) of Fig. 2. As we know, when $Q > 0$, the behavior of photon statistics is bunching, and when $Q < 0$, the behavior of photon statistics is anti-bunching. In Fig. 2(b), the $Q_p$ parameter shows the standard transition between bunching and anti-bunching when absorption occurs \[39, 41\]. When $\beta = 1$, however, the photon statistics shows bunching effect. The fluctuation of photon emission is enhanced, especially for the two bright branches on the $Q_p$ spectra as shown in Fig. 2(d). This means that the nature of photon emission statistics can be greatly affected by SGC.

**B. N-TYPE SYSTEM**

In previous section we investigate the vacuum-assisted transparency. If we apply the switching field, the double $\Lambda$-type system becomes the $N$-type system. The schematic diagram of this $N$-type four-level system is shown in panel (b) of Fig. 4. We study the GKE in $N$-type four-level system in this subsection, and we compare with the experimental results of Ref. \[12\]. Some interesting properties, such as the photon switching, frequency conversion etc are investigated by employing this system \[10, 22\]. It is shown that the process of photon emission is different with that in the double $\Lambda$ system: the nonlinear Kerr absorption occurs while the stability of the dark state within the EIT is destroyed. With the effects of SGC, however, the destroyed dark state can be

\[
\Delta_p = \Delta_c, \quad \text{corresponding to the two-photon absorption process. For fixed detuning $\Delta_c$, there are usually three peaks of $I_p$ as the function of $\Delta_p$ since two dark states are induced in this system. Particularly, when $\Delta_c = 0.5\omega$, the central peak vanishes as the EIT occurs. Part of the similar processes are studied experimentally in the $^{87}$Rb atoms system \[33\] for particular coupling detunings $\Delta_c$.}

For the case of the SGC factor $\beta = 1$, the GDCs $\gamma_{314}$ and $\gamma_{324}$ cause new EIT process. From Fig. 2(c), we can see the two new EIT channels along the $\Delta_p$-axis for $\Delta_c = 0.5\omega$, and along the $\Delta_c$-axis for $\Delta_p = 0.5\omega$ in absorption line shapes. Physically, the GDCs $\gamma_{314}$ ($\gamma_{324}$) can cause destructive interference between the transitions $|3 \rangle \rightarrow |1(2)\rangle$ and $|4 \rangle \rightarrow |1(2)\rangle$ if the states $|3\rangle$ and $|4\rangle$ are equally excited. The dark state is induced as the destructive interference between states $|3\rangle$ and $|4\rangle$. This can also be viewed as the phenomenon of dark resonance \[43, 50, 51\].

These two new EIT processes are not the same with the usual EIT (the diagonal channel) because they are assisted by SGC. We name them as the “vacuum-assisted transparency” (VAT). Experimentally, for example, we can introduce another field $\Omega_0$ between the excited states $|3\rangle$ and $|4\rangle$ to simulate the effects of SGC, the quantum system of the $^{87}$Rb atom then seems to be “locked” by this field and the coupling field with $\Delta_c = 0.5\omega$, and the probe field can not disturb the $^{87}$Rb atom and form the totally transparent window. Also, we can control the transparency window by whether turning the field $\Omega_0$ on or by changing its strength.

To understand the dynamics in this process, as an example, we analyze the VAT channel along the $\Delta_p$-axis for $\Delta_c = 0.5\omega$. When $\Delta_c = 0.5\omega$, for any $\Delta_p$ there is no absorption of the probe field. The reason is that the population trapping happens. When the atom is excited (except when the detuning $\Delta_p = 0.5\omega$), the population $\rho_{11}$ transfers to other three states, and they can not jump back to the ground state again due to influences of SGC. The trapping is controlled by the coupling field and GDCs. Specially, the populations $\rho_{33}$ and $\rho_{44}$ ($\rho_{33} = \rho_{44}$) are in proportion to the strengths of coupling field $\Omega_c$, while the population $\rho_{22}$ is in inverse proportion to $\Omega_c$. The process for $\Delta_p = 0.5\omega$ is different since the usual EIT channel is induced. The population is almost trapped in the initial ground state $(1)$ in our calculation. The difference between the processes of EIT and VAT means that we can control the population transfer \[37\] by turning the detuning of the coupling field $\Delta_c$. This process of population trapping is similar with the studies in Refs. \[29, 30, 55\]. In the four-level system in Refs. \[29, 30, 55\], two close-lying excited states couple to another auxiliary state by a driving field, and decay to the single ground state. In our system, the difference is that the coupling field and probe field can perform the EIT channel, we can combine the effects of EIT and SGC together, and switch between EIT ($\beta = 0$) and VAT ($\beta \neq 0$). In addition, if the coupling field is turned off, there will be no transparency even though SGC exists. That is to say, the coupling field is necessary to induce the VAT channel.

The characters of $Q_p$ parameter are plotted in panels (b) and (d) of Fig. 2. As we know, when $Q > 0$, the behavior of photon statistics is bunching, and when $Q < 0$, the behavior of photon statistics is anti-bunching. In Fig. 2(b), the $Q_p$ parameter shows the standard transition between bunching and anti-bunching when absorption occurs \[39, 41\]. When $\beta = 1$, however, the photon statistics shows bunching effect. The fluctuation of photon emission is enhanced, especially for the two bright branches on the $Q_p$ spectra as shown in Fig. 2(d). This means that the nature of photon emission statistics can be greatly affected by SGC.
weak probe field is set on transition. The behavior of the photon emission broadens, which reflects the influence of the strengths of absorption line shapes. The Rabi frequency $\Omega$ is in relation to the EIT signal when the switching field is turned off. As the switching field $\Omega$ increases from 11MHz to 24MHz, the absorption line shape $I_p$ and $Q_p$ spectra show the power broaden, which reflects the influence of the strengths of the coupling filed. The behavior of the photon emission at resonance shows anti-bunching. In contrast, when the EIT occurs at $\Delta_p = 0$, the behavior of photon emission shows bunching. And, there is the sharp “hole” in $Q_p$ spectra which is shown in the inset of Fig. (b). The reason for this “hole” is that the photon emission stops once the dark state is formed.

For this system, based on the $^{87}\text{Rb}$ atom, we set the states as $|5^2S_{1/2}, F = 1\rangle = |1\rangle$, $|5^2S_{1/2}, F = 2\rangle = |2\rangle$, $|5^2P_{1/2}, F' = 1\rangle = |3\rangle$, and $|5^2P_{1/2}, F' = 3\rangle = |4\rangle$. The weak probe field is set on transition $|3\rangle \rightarrow |1\rangle$, the strong coupling field is set on transition $|3\rangle \rightarrow |2\rangle$, the third switching field is set on transition $|4\rangle \rightarrow |2\rangle$. The Rabi frequencies are noted as $\Omega_{13} = \Omega_p$, $\Omega_{23} = \Omega_c$, $\Omega_{24} = \Omega_s$. The detuning frequencies are defined as $\Delta_p = \omega_p - \omega_{31}$, $\Delta_c = \omega_c - \omega_{32}$, $\Delta_s = \omega_s - \omega_{42}$. After these preparations, the equations of generating function of Eq. (11) for the $N$-type system are written as follows:

$$
\dot{G}_{11} = 2s(\gamma_{31}G_{33} + \gamma_{314}G_{34} + \gamma_{314}G_{44} + \gamma_{41}G_{44}) - i \frac{\Omega_p}{2}(G_{13} - G_{31}), \\
\dot{G}_{22} = 2(\gamma_{32}G_{33} + \gamma_{324}G_{34} + \gamma_{324}G_{44} + \gamma_{42}G_{44}) - i \frac{\Omega_c}{2}(G_{23} - G_{32}) - i \frac{\Omega_s}{2}(G_{24} - G_{42}), \\
\dot{G}_{33} = -2\Gamma_3G_{33} - \Gamma_{34}(G_{34} + G_{43}) - i \frac{\Omega_p}{2}(G_{31} - G_{13}) - i \frac{\Omega_s}{2}(G_{32} - G_{23}), \\
\dot{G}_{44} = -2\Gamma_4G_{44} - \Gamma_{34}(G_{34} + G_{43}) - i \frac{\Omega_s}{2}(G_{42} - G_{24}), \\
\dot{G}_{12} = -i(\Delta_p - \Delta_c)G_{12} - i \frac{\Omega_p}{2}(G_{13} + \Omega_cG_{14} - \Omega_pG_{32}), \\
\dot{G}_{13} = -i\Delta_pG_{13} - \Gamma_{34}G_{13} - \Gamma_{34}G_{14} - i \frac{\Omega_p}{2}(G_{11} - G_{33}) - i \frac{\Omega_c}{2}G_{12}, \\
\dot{G}_{14} = -i(\Delta_p - \Delta_c + \Delta_s)G_{14} - \Gamma_{34}G_{14} - \Gamma_{44}G_{14} - i \frac{\Omega_s}{2}(G_{12} - \Omega_pG_{34}), \\
\dot{G}_{23} = -i\Delta_cG_{23} - \Gamma_{34}G_{23} - \Gamma_{34}G_{24} - i \frac{\Omega_c}{2}(G_{22} - G_{33}) - i \frac{\Omega_s}{2}(G_{21} - \Omega_cG_{34}), \\
\dot{G}_{24} = -i\Delta_sG_{24} - \Gamma_{34}G_{24} - \Gamma_{44}G_{24} - i \frac{\Omega_s}{2}(G_{22} - G_{44}) + i \frac{\Omega_c}{2}G_{24}, \\
\dot{G}_{34} = -i(\Delta_s - \Delta_c)G_{34} - \Gamma_{34}(G_{33} + G_{44}) - (\Gamma_3 + \Gamma_4)G_{34} - i \frac{\Omega_s}{2}(G_{32} - \Omega_pG_{41} - \Omega_cG_{24}), \\
$$

and the other elements not included in Eq. (13) satisfy the complex conjugate relation: $\dot{G}_{ij}^* = G_{ji}^*$. The results of the GKE for weak probe field are shown in Figs. 3(a) and (c) and 4. The panels (a) and (c) are absorption line shapes as $|3\rangle \rightarrow |1\rangle$ and the other elements not included in Eq. (13) satisfy the complex conjugate relation: $\dot{G}_{ij}^* = G_{ji}^*$. The results of the GKE for weak probe field are shown in Figs. 3(a) and (c) and 4. The panels (a) and (c) are absorption line shapes as $|3\rangle \rightarrow |1\rangle$ and the other elements not included in Eq. (13) satisfy the complex conjugate relation: $\dot{G}_{ij}^* = G_{ji}^*$.

In Fig. 3, we show the EIT and the GKE in this system. Panels (a) and (c) are absorption line shapes $I_p$, panels (b) and (d) are $Q_p$ parameter. The blue and red crosses are the experimental results of Ref. 12, the solid lines and dashed-dot lines are our theoretical results. The experiment of Ref. 12 is carried out in a vapor-cell magneto-optic trap (MOT). The trapped Rb atom clouds is about 1mm in diameter and contains about 2 x 10^5 Rb atoms. The Rb atom vapor pressure is about 10^-9Torr. In the experiment of Ref. 12, there is no effect of SGC, that is, the SGC factor $\beta = 0$. As shown in the figure, our theoretical results and experimental results are in agreement well [60]. Fig. 3(a) and (b) show the standard EIT signal when the switching field is turned off. As the Rabi frequency $\Omega_c$ increases from 11MHz to 24MHz, the absorption line shape $I_p$ and $Q_p$ spectra show the power broaden, which reflects the influence of the strengths of the coupling filed. The behavior of the photon emission at resonance shows anti-bunching. In contrast, when the EIT occurs at $\Delta_p = 0$, the behavior of photon emission shows bunching. And, there is the sharp “hole” in $Q_p$ spectra which is shown in the inset of Fig. 3(b). The reason for this “hole” is that the photon emission stops once the dark state is formed.

When the switching field $\Omega_p$ is turn-on, there is absorption at $\Delta_p = 0$ as shown in Fig. 3(c). The two absorption sidebands are the usual Aulter-Townes (AT) doublets, and the central peak is the Kerr nonlinear absorption. There is no “hole” on the $Q_p$ spectra since the EIT is destroyed in this process. We show $Q_p$ parameter for the strengths of probe field $\Omega_p = 15$MHz by using dashed green line in Fig. 3(d). This result is not the same with those under the usual condition where anti-bunching behavior can not be captured as the strengths of the probe field increases [43, 49]. And the anti-bunching behavior of photon emission holds on as the strengths of the probe field $\Omega_p$ increases. In other words, the strengths of the probe field can not change the anti-bunching behavior. This stable anti-bunching behavior of photon emission demonstrates the ability of photon switching, and that the $N$-type system based on the GKE can serve as the few photon emitter [70].

Furthermore, we show the absorption line shapes $I_p$ (panels (a) and (c)) and $Q_p$ parameter (panels (b) and
FIG. 3: (Color online) The absorption line shapes $I_p$ (panels (a) and (c)) and Mandel’s $Q_p$ parameter (panels (b) and (d)) of the N-type system. Panels (a) and (b) is for the switching field turn-on, panels (c) and (d) is for the switching field turn-off, $\Omega_s = 14$MHz. The blue and red crosses are the experimental results in Fig. 3 of Ref. [12]. The insets in panels (a) and (c) show the fine structure of the hole on the $Q_s$ spectra for the solid line around $\Delta_p = 0$. The inset shows the fine structure of the hole on the $Q_p$ spectra for the solid line around $\Delta_p = 0$. The parameters are $\Omega_p = 15$MHz, $\Omega_c = 24$MHz, $\Delta_p = 15$MHz, $\Omega_s = 14$MHz.

FIG. 4: (Color online) The absorption line shapes $I_p$ (panels (a) and (c)) and Mandel’s $Q_p$ parameter (panels (b) and (d)) of the N-type system as the functions of Rabi frequencies $\Omega_c$ (panels (a) and (b)), $\Omega_s$ (panels (c) and (d)) and detuning frequency $\Delta_p$. The parameters are $\Omega_p = 1.5$MHz, $\Omega_s = 14$MHz (panels (a) and (b)); $\Omega_p = 1.5$MHz, $\Omega_s = 11$MHz (panels (c) and (d)). The other parameters are the same with Fig. 3.

FIG. 5: (Color online) The absorption line shapes $I_p$ (panels (a) and (c)) and Mandel’s $Q_p$ parameter (panels (b) and (d)) of the N-type system. $\Omega_p = 1.5$MHz, $\Omega_s = 25$MHz, $\Omega_c = 10$MHz (panels (a) and (b)), 25MHz (panels (c) and (d)). The SGC factor $\beta = 0$ (black line), $\beta = 0.5$ (green line), $\beta = 0.9$ (red line), $\beta = 1$ (blue line). The other parameters are the same with Fig. 4. The insets in panels (a) and (c) show the height of the Kerr nonlinear absorption peak of line shapes as the function of $\beta$, the inset in panel (d) shows Mandel’s $Q_p$ parameter near resonance $\Delta_p = 0$.

For small $\Omega_s$ there is only AT doublets of absorption line shapes $I_p$, this is not the same with the above case. It is shown in Fig. 4 (c). Under this condition, the Kerr nonlinearity is trivial, which can also be realized for far off resonance of the switching field. As $\Omega_s$ increases, however, the central peak at $\Delta_p = 0$ increases nonlinearly until its steady value. Physically, this nonlinear increase is determined by the strengths of the coupling field $\Omega_c$.
and the steady process of $I_p$ is related to the probe field. Another influence of switching field is, the splitting of the AT doublets gets bigger when $\Omega_s$ increases. The reason is that the splitting between the dressed states can also be affected by the switching field $\Omega_s$, this splitting is $\propto \sqrt{\Omega_c^2 + \Omega_s^2}$. Our numerical results verify this behavior.

In Fig. 5(b) and (d) we show the spectra of Mandel’s $Q_p$ parameters. For the central Kerr absorption at $\Delta_p = 0$, one can see magnitude of $Q_p$ parameters decreases with $\Omega_c$ and increases with $\Omega_s$. The reason is that the coupling field can inhibit the Kerr absorption process, while the switching field can enhance it. However, $Q_p$ parameters stay minus at resonance, which means the strengths of the coupling field $\Omega_c$ or the switching field $\Omega_s$ can not change the natures of the photon statistics: the anti-bunching or the bunching.

In the above consideration we do not include the effect of SGC. In fact, it is also possible to introduce the effect of SGC into the nonlinear Kerr absorption. The results for different SGC factor $\beta$ are shown in Fig. 5. The top row is absorption line shapes $I_p$, and the bottom row is $Q_p$ parameter.

To better show GKE, we chose the parameters to make the one-photon process obvious. In Fig. 5(a) and (b), we show the results of $\Omega_c = 25$MHz, $\Omega_s = 10$MHz. We can see from the figure, the Kerr absorption is more obvious than that of AT doublets. As the SGC factor $\beta$ increases (from 0 to 1), the AT doublets are being restrained. The central Kerr peak, however, is “coherently narrowed and enhanced” (see Fig. 5(a)). The behavior of the Kerr absorption shows nonlinear change with the increasing of $\beta$, as shown in the inset of Fig. 5(a). The values of $Q_p$ parameters (panel (b)) become negative big at $\Delta_p = 0$ as $\beta$ increases, which means that the anti-bunching effect becomes more obvious. Also, $Q_p$ spectra becomes narrow around $\Delta_p = 0$.

We further consider another special case: $\Omega_c = \Omega_s = 25$MHz. The results are shown in Fig. 5(c) and (d). We see that the separation of the AT doublets increases to 35.36MHz. The Kerr absorption peak as the function of $\beta$ is shown in the inset of Fig. 5(c). Its behavior in this case is different with that of the above case. What is particular in this case is the central Kerr absorption goes to zero when $\beta = 1$. That is, the nonlinear Kerr absorption is eliminated due to SGC, it is shown as the blue line in Fig. 5(c). This can also be viewed as the retrieval of dark state in the system. The reason is that there exists the quantum interference between the one-photon and two-photon processes for $\beta = 1$. For $\beta = 0$, however, there is no this quantum interference. In addition, the behavior of photon emission is affected by SGC: $Q_p$ parameter changes from negative to positive values when $\beta$ gets big, which is different with the above case. The inset in panel (d) shows this change at the detuning $\Delta_p = 0$.

IV. BRIEF CONCLUSION

In this work we investigate the effects of SGC on the electromagnetically induced transparency (EIT) and the giant Kerr effect (GKE) of four-level quantum system of the $^{87}$Rb atom driven by external cw laser fields.

In our study, we show the structure of absorption line shapes in the detuning space for the double $\Lambda$-type system. The usual EIT means that we can control the quantum system (such as the $^{87}$Rb atom) by employing the strong coupling field, and there is no absorption when the weak probe field is introduced under the condition of two-photon resonance. With the effect of SGC, there exist new EIT channels, we note them as the “vacuum-assisted transparency” (VAT). It means that we can use external fields to lock the system, so that there is no absorption when the probe field is introduced even beyond the two-photon resonance condition. The transparency window crosses the whole detuning range of the probe field. Also, this could be more convenient to operate in experiment than the usual EIT setup.

The coupling field $\Omega_c$ and the switching field $\Omega_s$ play the different role in GKE for the $N$-type system: the former one can inhibit the nonlinear absorption, while the later one can enhance it. If there exists SGC in the system, the nonlinear Kerr absorption can be either narrowed or eliminated under different driven conditions. When the nonlinear absorption is completely eliminated, the dark state can be repaired by SGC.

For the photon statistics, several kinds of behaviors of Mandel’s $Q$ parameter, such as the “hole” of the dark state, the steady anti-bunching of the photon switching, the transition between bunching and anti-bunching near resonance, and the big fluctuation due to SGC are also studied.

Based on this work, the dynamics of other type four level systems, such as the $Y$-type, the inverse $Y$-type systems can be investigated. Also, this study will be of interest for further investigation in few photon processes, spontaneous emission cancellation, etc.
