The evolution of entanglement entropy in quantum circuits composed of Haar-random gates and projective measurements shows versatile behavior, with connections to phase transitions and complexity theory. We reformulate the problem in terms of a classical Markov process for the dynamics of bipartition purities and establish a probabilistic cellular-automaton algorithm to compute entanglement entropy in monitored random circuits on arbitrary graphs. In one dimension, we further relate the evolution of the entropy to a simple classical spin model that naturally generalizes a two-dimensional lattice percolation problem. We also establish a Markov model for the evolution of the zeroth Rényi entropy and demonstrate that, in one dimension and in the limit of large local dimension, it coincides with the corresponding second-Rényi-entropy model. Finally, we extend the Markovian description to a more general setting that incorporates continuous-time dynamics, defined by stochastic Hamiltonians and weak local measurements continuously monitoring the system.

Recent progress in creating and manipulating many-qubit devices led to their ability to arguably attain quantum supremacy, i.e., to exhibit dynamics that is not efficiently simulable on classical computers [1–3]. Existing supremacy proposals include circuit models that utilize randomly generated local gates to create classically irreproducible quantum multi-qubit correlations [4, 5]. Random circuits can be characterized by a rapid growth of entanglement across the system [6–9], and even though high entanglement alone does not guarantee hardness of classical simulation [10, 11], the generation of entangled states is key to achieving such hardness in many cases [12]. Different behavior can be found if a random circuit is affected by measurements that project and thus disentangle individual qudits. Under persistent random measurements, a competition between entanglement production and reduction mechanisms leads to a phase transition [13–25] separating phases with area- and volume-law entanglement, similar to known dynamical quantum phase transitions in Hamiltonian systems [26–29]. Therefore, the evolution of entanglement in monitored random circuits exhibits versatile behavior associated with a range of fields from complexity theory to condensed matter physics.

In this work, we study the dynamics of entanglement in a wide class of random circuits under the combined effect of unitary gates and measurements. Starting with a random-walk model for entanglement growth in 1D unitary circuits, we generalize our approach to a Monte Carlo algorithm for computing the average entanglement entropy on arbitrary graphs in the presence of both unitary evolution and single-qudit measurements. Furthermore, our approach can be mapped to a dynamical lattice percolation problem, which, in the limit of infinite qudit dimension, maps to a static percolation transition [15, 17, 20]. We also study a continuous-time analogue of random circuits [30–33] in which the system evolves under a stochastic local Hamiltonian and is subject to dephasing and continuous weak measurements [34–36]. We thus introduce the study of random quantum circuits to a rich arena of weak-measurement physics boasting both applied and foundational results [37–40].

Mapping of monitored quantum circuits to classical models has been studied recently using the replica trick for both closed [9, 41] and monitored [23] systems. The theoretical description is simplified in the limit of large qudit dimension $q \gg 1$ [9, 23]. In Refs. [7, 42], it was shown that, in the large-$q$ limit, the evolution of Rényi entropies in random unitary circuits can be described by a Kardar–Parisi–Zhang-type (KPZ-type) equation [43]. Hydrodynamic descriptions of random unitary circuits are also discussed in Refs. [8, 44, 45]. In the presence of projective measurements, mapping to spin models connects the entanglement phase transitions to the percolation criticality and conformal field theories [15, 46]. The measurement-induced entanglement phase transition is also related to the encoder-decoder field theories [15, 46]. The measurement-induced entanglement phase transition is also related to the encoder-decoder field theories [15, 46]. The measurement-induced entanglement phase transition is also related to the encoder-decoder field theories [15, 46].

Hydrodynamic descriptions of random unitary circuits are also discussed in Refs. [8, 44, 45]. In the presence of projective measurements, mapping to spin models connects the entanglement phase transitions to the percolation criticality and conformal field theories [15, 46].

We consider a generic circuit acting on $q$-dimensional qudits and consisting of Haar-random gates and projective single-qudit measurements. As a measure of entanglement between a specified subsystem $A$ and the rest of the qudits, we use average Rényi entropy $S_2[A] \equiv -\langle \log \text{Tr}_A(\rho_A^2) \rangle$, where $\langle \ldots \rangle$ denotes an average with respect to circuit realizations and $\rho_A$ is the reduced density matrix of $A$. In order to compute the average, we apply the annealed approximation, $S_2[A] \simeq -\log P_A$, where $P_A \equiv \langle \text{Tr}_A(\rho_A^2) \rangle$ is the (average) purity. This approximation is exact for Haar-random states in the limit of large system size [47–49]. We demonstrate in this work that this approximation is also remarkably accurate in application to random circuits.

To compute the Rényi entropy, we focus on the vector $P = \{P_G : G \in F\}$ consisting of purities of all possible
subsystems $G$ of the full system $F$. Below we mostly focus on the linear discrete-time Markovian evolution

$$P(t+1) = \mathcal{L}P(t),$$

where $\mathcal{L}$ is a time-dependent Liouvillian (see also Ref. [50]). In the following sections, we will show the relevance of this model to random circuits.

**Random Circuits.**—Consider the evolution of a pure state $|\psi\rangle$ under a single Haar-random gate $U$ supported on subset $\omega$, $|\psi'\rangle = U|\psi\rangle$. The resulting (gate-averaged) purity of an arbitrary subset $G$ for the state $|\psi'\rangle$ is determined [see Supplemental Material (SM) [51], Sec. I] by the purities for $|\psi\rangle$ via

$$P_G' = c_- P_{G\setminus\omega} + c_+ P_{G\cup\omega},$$

where $c_- = d_1(d_2-1)/\langle d_2-1 \rangle$, $c_+ = d_2(d_2-1)/\langle d_2-1 \rangle$, $d_1 = d_{G,G}$, and $d_2 = d_{G} \cdot d_G$ [52]. For two-qudit gates with $d_1 = d_2 = q$, we obtain $c_- = c_+ = q/(q^2 + 1)$. Coefficients $c_+$ and $c_-$ are the only non-zero elements in the Liouvillian matrix $\mathcal{L}$ in Eq. (1) representing a single random gate. For more than one gate, the total Liouvillian is the product of individual gate Liouvillians in reverse chronological order.

We now consider a projective measurement performed on a single qudit $\Omega$ of an observable $O = \sum_i o_i \Pi_i$, where $\Pi_i$ are projectors satisfying $\Pi_i \Pi_j = \delta_{ij}$. A measurement with outcome $o_i$ projects the system onto $|\psi'\rangle = |\Pi_i \psi\rangle/\langle \Pi_i | \psi \rangle$. Since measurements are always “sandwiched” between Haar-random gates, without loss of generality, we replace the purities by their average over the basis of $O$, $P_G = \langle \text{Tr} \rho_{G,O} \rangle$. Applying the annealed approximation to $O_1/O_2 (\langle O_1/O_2 \rangle \simeq \langle O_1 \rangle/\langle O_2 \rangle)$, the post-measurement purity becomes

$$P_G' \simeq \frac{\langle \text{Tr} G(|\Pi_i \psi\rangle \langle \Pi_i \psi|^2) \rangle_O}{\langle \langle |\psi\rangle \langle \Pi_i | \psi \rangle^2 \rangle_O} = P_{G,O} + P_{G,O}/1 + P_{G,O}.$$ 

(3)

To express the combined non-linear evolution under Eqs. (2, 3) in terms of linear evolution, we define *unnormalized purities* $P$ evolving under $P(t+1) = \mathcal{L}P(t)$, where unitary dynamics is given by Eq. (2), while measurements are treated as the transformation $P_G = P_{G,O} + P_{G,O}$. Then, after an arbitrary number of unitary and measurement transformations, the physical purity vector is

$$P_G = \tilde{P}_G/\tilde{P}_F,$$

where $\tilde{P}_F$ is the unnormalized purity of the full system.

**Classical Models.**—The linearity of purity evolution enables the mapping of entanglement dynamics onto classical problems such as multi-particle random walks. As an illustration, consider a simple brickwork 1D unitary circuit [Fig. 1(a) without measurements]. It follows from Eq. (2) that the dynamics of bipartition purities $P_x$ parametrized by the cut position $x$ is a modified single-particle random-walk: $P_{x+1} = c(P_{x-1} + P_{x+1})$ for $x = 2n + t$ (mod 2), $n \in \mathbb{Z}$, and $c = q/(q^2 + 1)$. The Rényi entropies $S_q(x, t) = -\log P_x$ in the continuous limit then satisfy a noise-averaged KPZ equation

$$\partial_t S_x = \mu(\partial_x^2 S_x - (\partial_x S_x)^2) + \beta,$$

where $\beta = \log((q^2 + 1)/2q)$ and $\mu = \beta/(\log q)^2$ (see SM Sec. III [51]). The long-time asymptotic solution of this hydrodynamic equation, subject to vanishing boundary conditions at the endpoints of the 1D qudit chain, is

$$S_2(t \to \infty, x) \to \log \left[ \frac{\cosh(\alpha N/2)}{\cosh(\alpha(x - N/2))} \right],$$

(6)

where $\alpha = \sqrt{\beta/\mu} = \log q$ and $N$ is the number of qudits. The maximum value of the entropy at the center of the chain, $S_2(t \to \infty, x = N/2) \approx \alpha N/2 - 2 + O(\exp(-\alpha N))$, exhibits volume-law scaling. The precision of the hydrodynamic approximation for $q = 2$ is illustrated in Fig. 2(a).

In more general settings, the number of partitions involved in the dynamics of purities $P_A$ (or $\tilde{P}_A$) grows exponentially in time. To describe such processes, we consider a sequence of $n$ circuit layers, each described by a sparse Liouvillian $L_k$, sorted in reverse chronological order. Let us define a collection of neighboring sets $N_k[G] = \{G': L_{G,G'} \neq 0\}$ and multiple trajectories $G = \{G_1 \to G_2 \cdots \to G_n\}$ such that $G_{k+1} \in N_k[G_k]$, and $G_1 = A$. Assuming the system is initialized in a product state, i.e., $P_G(0) = 1$ for all $G$, the (unnormalized) purity after $n$ circuit layers is

$$\tilde{P}_A = \sum_G P_G, \quad P_G = \prod_{k=0}^{n-1} L_{G_k,G_{k+1}}.$$ 

(7)

The sum in Eq. (7) can be represented by a generalized random walk. Following a Markov chain Monte Carlo (MCMC) algorithm, instead of listing all possible trajectories, we consider their probabilistic generation, choosing $G_{k+1}$ from the set $N_k[G_k]$ with probability $\pi_k = L_{G_k,G_k}/T_k$, where $T_k = \sum_{G \in N_k[G_k]} L_{G_k,G_k}$. In the MCMC scheme, the purity $\tilde{P}_A$ in Eq. (7) is approximated by the sampled average $\tilde{P}_A \approx \langle P^{MC}_A \rangle_g = \langle \prod_k T_k \rangle g$. In practice, in order to estimate $\tilde{P}_A$, one needs an average over a large number of trajectories due to the broad distribution of $P^{MC}_A$. Nevertheless, simulations show that this number can be significantly smaller than the full number of trajectories $g$.

For simulation purposes, the MCMC algorithm can be mapped to a probabilistic classical cellular automaton [53]. It is instructive to start with the monitored 1D brickwork circuit shown in Fig. 1(a). We describe each unitary and measurement layer by a Liouvillian $L^u$ and $L^m$, respectively. The colored pattern in Fig. 1(b) illustrates the dynamics of the corresponding cellular automaton evolving from top to bottom generating a trajectory, where each cell represents a qudit. Blue cells in
Each row denote the qudits forming $G_k \in \mathcal{G}$, where $\mathcal{G}$ is a trajectory formed by alternating $\mathcal{L}_k^u$ and $\mathcal{L}_k^m$.

Each unitary layer Liouvillian $\mathcal{L}_k^u$ can be converted into a rule: all distinct-color pairs of cells affected by a Haar-random two-qudit unitary in this layer switch to the same color, chosen by a coin toss for each gate. Every such switch contributes a factor $T_k = 2q/(q^2 + 1)$ to the corresponding amplitude $P^\text{MC}_k$. A measurement layer $\mathcal{L}_k^m$ is equivalent to a color flip of each cell representing a measured qudit with probability $\tau_k^m = 1/2$, with no contribution to $P^\text{MC}_k$, i.e. $T_k = 1$. The method can be used as a fast sampling algorithm producing purities [see Fig. 2(b)] and applies to arbitrary graphs [see Fig. 2(c) showing MCMC results for 2D]. The MCMC method is particularly useful for analysing measurement-induced entanglement phase transitions. For example, Fig. 2(d) illustrates entropy growth in a 1D brickwork circuit with measurements affecting each qudit with probability $p$ at every layer; MCMC shows excellent agreement with exact numerics. The algorithm can be used to reach larger system sizes enabling an estimate of the critical $p$ and critical exponents, as illustrated in Fig. 2(d).

Instead of the MCMC algorithm, we can alternatively relate $\tilde{P}_A$ to a partition function of a classical Hamiltonian $H$, with trajectories $\mathcal{G}$ mapped to energy levels $E[\mathcal{G}] \in \text{spec}(H)$,

$$\tilde{P}_A = \sum_\mathcal{G} \exp(-\beta E[\mathcal{G}]) = \text{Tr} \left( P \exp(-\beta H) \right),$$

where $\beta = \log((q^2 + 1)/2q)$ is an effective inverse temperature, and $P$ is a projector onto the levels $E[\mathcal{G}]$.

For the monitored 1D brickwork circuit, such a classical model can be constructed as follows (see also SM Sec. IV [51]). Let us combine each pair of unitary and measurement layers into a single Liouvillian $\mathcal{L}_k^\text{em}$ coupling $G_k'$ to $G_{k+1}'$, where the full trajectory $\mathcal{G} = \{G_1' \rightarrow G_2' \cdots \rightarrow G_n'\}$ includes only odd-time bipartitions, $G_k' = G_{2k-1}'$. Then, for any trajectory $\mathcal{G}$, bipartitions propagate on a square lattice shown in Fig. 1(c), representing a classical analogue of the Feynman checkerboard [54]. We associate a classical variable $Z_i = 1$ to a square if it is part of $G_k'$ [blue squares in Fig. 1(c)], while the rest have $Z_i = -1$ (white squares); domain walls (red) separate blue squares from white ones. Furthermore, any edge $(i, j)$ separating adjacent squares $i$ and $j$ and situated below a measurement in Fig. 1(c) is assigned an additional degree of freedom $J_{ij} = 1$ (solid line) or $J_{ij} = -1$ (dashed line). For all other edges, we set $J_{ij} = 1$. In this setting, the classical Hamiltonian and projector in Eq. (8) are

$$H = \frac{1}{2}N_0 - \frac{1}{4} \sum_{\langle i,j \rangle} J_{ij} Z_i Z_j,$$

$$\mathcal{P} = \mathcal{P}_A \prod_{i,j,k \in \Sigma_3} \left( 1 - \frac{1}{4} (Z_k - J_{ik} Z_i)(Z_k - J_{kj} Z_j) \right),$$

where $(i,j)$ is the sum over all $N_0$ edges, $\mathcal{P}_A = \prod_{k \in \mathcal{A}} \frac{1}{2}(1+Z_k)$ projects the top squares onto the bipartition configuration $A$, and $\Sigma_3$ are all possible oriented 3-cell groups, as shown in Fig. 1(c). This model applies to periodic boundary conditions (for open boundary conditions, see SM Sec. IV [51]). The Hamiltonian $H$ is simply equal to the total number of solid red edges.
edges plus the total number of dashed black edges.

**Connection to Hartley entropy.**—The dynamics of the Hartley entropy, defined as the zeroth Rényi entropy $S_0[A] = \log(\rho_A)$, where $R_G = \text{rank}(\rho_G)$, is typically qualitatively different from Rényi entropies of order $n \geq 1$ [17]. Nevertheless, we show that $S_0$ has deep connections to the 2nd Rényi entropy $S_2$. Under a generic unitary transformation supported on $\omega$, $G \subseteq \omega \neq \emptyset$ and $\omega \setminus G \neq \emptyset$, the rank follows non-linear Markovian dynamics (see SM Sec. II [51]):

$$R_G' = \frac{R_G \wedge R_{G \wedge \omega}}{R_{G \Delta \omega}} \min(\delta_{G \wedge \omega}, \delta_{G \wedge \omega}, \delta_{G \wedge \omega}, \delta_{G \wedge \omega}),$$

(10)

where $G \Delta \omega \equiv (G \cup \omega) \setminus (G \cap \omega)$. The effect of a measurement on a percolated lattice, as previously suggested in Ref. [17]. Notably, $S_0$ can also be written as $S_0[A] = \log(q) \min_{G} E[G]$, where $E[G]$ is the spectrum of the Hamiltonian in Eq. (9) for configurations satisfying $P[G]$ as 1. As a consequence, in the limit $q \to \infty$, entropies $S_0$ and $S_2$ coincide, given that, in the limit $\beta \to \infty$, the partition function in Eq. (8) reduces to $S_2[A] \approx \beta \min_{G} E[G]$ with $\beta \sim \log q$.

In the hydrodynamic approximation, Hartley entropy for 1D unitary brickwork circuits evolves according to the continuum limit of Eq. (10) (see SM Sec. III [51]):

$$\partial_t S_0 = \frac{1}{2} \partial_x^2 S_0 - | \partial_x S_0 | + \alpha,$$

(12)

where $\alpha = \log q$. For product initial states, the time-dependent solutions of Eqs. (12) and (5) coincide in the limit $q \to \infty$ at scales $x \gg 1$. Furthermore, the stationary solution of Eq. (12) for an initial product state and open boundary conditions $S_0(x = 0) = S_0(x = N) = 0$ is $S_0(t \to \infty, x) = \alpha(N/2 - |x - N/2|)$, exhibiting the same volume-law entanglement as $S_2$.

**Continuous Evolution.**—To complete the analysis of the evolution of purity, we propose a continuous-time version of monitored random circuits. We consider a local stochastic Hamiltonian $H(t) = \sum_i \mathbb{I}_{\mathcal{F}_{i,\omega_i}} \otimes h_i(t)$, where individual local terms $h_i(t)$ are stochastic Gaussian-ensemble matrices supported on respective sets $\omega_i$. The corresponding matrix elements $h_{ij,\mu\nu}^{t_0}$ of $h_i$ satisfy $\langle h_{ij,\mu\nu}^{t_0}(t)h_{ij,\mu'\nu'}(t') \rangle_h = \frac{1}{2} \alpha_i(t) \delta_{ij} \delta_{\mu\nu} \delta_{\mu'\nu'} \delta(t - t')$ for some positive functions $\alpha_i(t)$. As a model for monitoring, we consider continuous weak measurements [55–58] performed for arbitrary single-qudit physical observables $O_j$ (acting on site $\Omega_j$) that yield a combined non-linear equation

$$\frac{d}{dt} |\psi\rangle = -i H(t) |\psi\rangle$$

(13)

$$+ \sum_j \left[ -\kappa_j \delta O_j(\psi) |\psi\rangle \right]^{2} + \kappa_j\delta O_j(\psi) \xi_i(t) |\psi\rangle,$$

where $\delta O_j(\psi) = O_j - \langle \psi | O_j | \psi \rangle$, $\xi_i(t)$ are independent stochastic variables satisfying $\langle \xi_i(t) \xi_j(t') \rangle = \delta_{ij} \delta(t - t')$, and $\kappa_j$ characterize the strength of the coupling to the measurement apparatus [34–36]. Similar to projective measurements, continuous measurements also reduce
entanglement in the system, leading to a competition with unitary evolution [13]. We note that what follows holds even if we replace our time-independent $O_j$ with $O_j(t) = V_j(t)O_j V_j^\dagger(t)$, where $V_j(t)$ is an arbitrary time-dependent unitary, which changes the measurement basis.

We are looking for a closed set of equations for the purity vector $\mathbf{P}$, which evolves according to $\partial_t \mathbf{P} = \mathcal{L}_t^u(\mathbf{P}) + \mathcal{L}_m^u(\mathbf{P})$. Here, the unitary Liouvillian obeys (see SM Sec. V [51])

$$\mathcal{L}_t^u(\mathbf{P})|_G = -\sum_i \alpha_i \left( P_G + \frac{P_G \Delta \omega_i}{\omega} - \frac{P_G \omega_i}{\omega^2} \right),$$

(14) As expected, for a single time-independent term $h_i$, the steady-state of the Liouvillian in Eq. (14) yields the discrete-time evolution in Eq. (2) [51].

The measurement Liouvillian obeys

$$\mathcal{L}_m^u(\mathbf{P})|_G = \sum_{j: \Omega, j \in F \cup G} \zeta_j C_{G, \Omega_1} + \sum_{j: \Omega \in G} \zeta_j C_{F \setminus G, \Omega_1},$$

(15) where $\zeta_j = 8 k_B \text{Tr} \Omega_j O_j^2 / (q^2 - 1)$, the measure of correlation $C_{S, \Omega} = \left\{ \| \rho_{S, \Omega} - \rho_S \otimes \rho_T \|_2^2 \right\}$ encodes the state of the system, and $\| \cdot \|_2$ is the 2-norm. In the mean-field approximation, $C_{S, \Omega} \approx P_{S, \Omega} - P_S P_T$, leading to the desired closed set of equations for purities. Importantly, in this approximation, when only one qudit is measured, the steady-state of the Liouvillian in Eq. (15) yields the discrete-time annealed-approximation evolution in Eq. (3) [51].

**Outlook.**—In this work, we demonstrated that linear dynamics of purities arises in monitored random circuits and yields, under the annealed approximation, an algorithm for computing entanglement based on a mapping to dynamical percolated lattices. Many classical spin models with local interactions have efficient classical solutions requiring only polynomial resources. Can we establish this property for dynamical percolated lattices? Also, having established in this work a close correspondence between zeroth and second Rényi entropies, we conjecture such correspondence for other Rényi entropies.

**Note.**—During the preparation of this manuscript, a related preprint appeared [59] studying purities to analyze entanglement phase transitions in 1D circuits using mappings to a quantum spin model.

Supplemental Material for
“Classical Models of Entanglement in Monitored Random Circuits”
Oles Shtanko, Yaroslav A. Kharkov, Luis Pedro García-Pintos, and Alexey V. Gorshkov

In this Supplemental Material, we present details omitted in the main text. In particular, in Sec. I, we derive Eqs. (2,3) in the main text and analyze the accuracy of the annealed approximation. In Sec. II, we derive Eqs. (10,11) in the main text. In Sec. III, we derive Eqs. (5,6,12) in the main text. In Sec. IV, we derive Eqs. (8,9) in the main text. Finally, in Sec. V, we derive Eqs. (14,15) in the main text, analyze the accuracy of the mean-field approximation used to simplify Eq. (15), and show that Eqs. (14,15) can be used to derive Eqs. (2,3).

SECTION I: EVOLUTION OF RÉNYI ENTROPIES

In this section, we derive the evolution Equations (2,3) for averaged subsystem purities. We also analyze the accuracy of the annealed approximation used in the main text to connect Rényi entropies and averaged purities.

**Unitary gates.** Consider a single unitary gate $U$ supported on subset $\omega$. We are interested in finding the effect of $U$ on averaged purities. To perform this calculation, we divide the system into four subsets $A$, $B$, $C$, and $D$, as shown in Fig. S1(a), and introduce the corresponding matrix representation for the density operator $\rho$.

$$P_G' = \frac{\langle Tr_G(Tr_{F\setminus G}(U\rho U^\dagger))^2\rangle_{\text{circ},U}}{P_G} = \sum_{\alpha_k,\beta_k,\gamma_k,\delta_k} \langle \rho_{\alpha_1\beta_1\gamma_1\delta_1,\alpha_2\beta_2\gamma_2\delta_2,\alpha_3\beta_3\gamma_3\delta_3,\alpha_4\beta_4\gamma_4\delta_4} \rangle_{\text{circ}} \left\langle U_{\gamma_1\delta_1,\gamma_2\delta_2,\gamma_3\delta_3,\gamma_4\delta_4,\omega}^* \right| U_{\delta_1\gamma_1,\delta_2\gamma_2,\delta_3\gamma_3,\delta_4\gamma_4,\omega} \rangle, \tag{S.1}$$

where $\langle \ldots \rangle_U$ is the Haar average over $U$, while the average over the circuit $\langle \ldots \rangle_{\text{circ}}$ includes the average over circuit evolution preceding the application of $U$. For random circuits, the $\langle \ldots \rangle_U$ and $\langle \ldots \rangle_{\text{circ}}$ averaging can be separated because gate unitaries are sampled independently.

Correlation functions of Haar-random unitary matrix elements satisfy

$$\langle U_{a,d}^* U_{b,c}^* U_{a,d} U_{b,c}^* \rangle_U = \frac{1}{d^2-1} \left( \delta_{a,b} \delta_{c,d} + \delta_{a,c} \delta_{b,d} + \delta_{a,d} \delta_{b,c} - 1 \right). \tag{S.2}$$

Denoting $d_1 = d_{G\setminus \omega}$ and $d_2 = d_{\omega\setminus G}$, satisfying $d_\omega = d_1 d_2$, we obtain

$$P_G' = \frac{1}{d^2_G-1} \left( d_1 d_2^2 P_{G\setminus \omega} + d_2 d_1^2 P_{\omega\setminus G} - \frac{1}{d_\omega} \left( d_1 d_2^2 P_{G\setminus \omega} + d_2 d_1^2 P_{\omega\setminus G} \right) \right) = \frac{1}{d^2_G-1} \left( d_1 (d_2^2-1) P_{G\setminus \omega} + d_2 (d_1^2-1) P_{\omega\setminus G} \right). \tag{S.3}$$

which is Eq. (2) in the main text. This expression works for both pure and mixed states of the full system.

**Measurements.** Consider a projective measurement of qudit $\Omega$. We express this measurement using a projector $\Pi = \Pi_0 U^\dagger$, where $\Pi_0^2 = \Pi_0$, $\mathrm{Tr} \Pi_0 = 1$, and $U$ is a Haar-random unitary supported on $\Omega$. We assume that the full system is in a pure state, $\rho = |\psi\rangle \langle \psi|$. Using the annealed approximation to take the expectation value of a ratio, we obtain

$$P_G' = \frac{\langle \mathrm{Tr}_G(\Pi |\psi\rangle \langle \psi|)^2 \rangle_{\Pi}}{\langle |\psi\rangle \langle \psi| \rangle^2_{\Pi}} = \frac{\tilde{P}_G'}{P_F'}. \tag{S.4}$$

Let us assume first that $\Omega \in G$. Then

$$\tilde{P}_G' = \frac{\langle \mathrm{Tr}_G(\rho G)^2 \rangle_{\rho,\Omega}}{\langle |\psi\rangle \langle \psi| \rangle^2_{\Pi}} = \frac{\langle \mathrm{Tr} (\rho U \Pi_0 U^\dagger)^2 \rangle_{\rho,U}}{\langle |\psi\rangle \langle \psi| \rangle^2_{\Pi}} = \frac{1}{d_\Omega-1} \left( \left( \mathrm{Tr} G_{\upepsilon \Omega}^2 (\mathrm{Tr} \Omega \Pi_0)^2 + \mathrm{Tr} G_{\upepsilon \Omega} (\mathrm{Tr} \Omega \rho G)^2 \mathrm{Tr} \Omega \Pi_0^2 - \frac{1}{d_\Omega} \left( \mathrm{Tr} G_{\upepsilon \Omega} (\mathrm{Tr} \Omega \rho)^2 \mathrm{Tr} \Omega \Pi_0^2 + (\mathrm{Tr} G \rho)^2 (\mathrm{Tr} \Omega \Pi_0)^2 \right) \right) \right)_{\rho} = \frac{1}{d_\Omega} \left( P_G + P_{G\setminus \Omega} \right). \tag{S.5}$$
The denominator of Eq. (S.4) can also be derived from Eq. (S.5) by taking $G$ can then use Eq. (S.5) to obtain $G$ gives a good estimate of the average entropy $S$. (a) Subdivision of the full system $F$ into four subsets $A = F \setminus (G \cup \omega)$, $B = G \setminus \omega$, $C = \omega \cap G$, and $D = \omega \setminus G$. (b) Matrix product structure in 1D systems corresponding to Eq. (S.10). Each square represents a matrix, while $N_i$ are local bond dimensions. (c) Most general MPS structure, where $N_{GG'}$ represents the local bond dimension between sets $G$ and $G'$. where we used the correlation function in Eq. (S.2).

The case when $\Omega \notin G$ can be approached in a similar fashion. Making use of the symmetry $\tilde{P}_{F\setminus G} = \tilde{P}_G$ for pure states, it is convenient to consider the purity $\tilde{P}_{F\setminus G}'$ of the complement of $G$ instead of $\tilde{P}_G$ itself. Since $\Omega \in F \setminus G$, we can then use Eq. (S.5) to obtain

$$\tilde{P}_G = \tilde{P}_{F\setminus G}' = \frac{1}{d_\Omega + 1} \left( P_{F\setminus G} + P_{(F\setminus G)\setminus \Omega} \right) = \frac{1}{d_\Omega + 1} \left( P_G + P_{G\setminus \Omega} \right).$$

(S.6)

Both cases can be summarized as

$$\tilde{P}_G' = \frac{1}{d_\Omega + 1} \left( P_{G\setminus \Omega} + P_{G\setminus \Omega} \right).$$

(S.7)

The denominator of Eq. (S.4) can also be derived from Eq. (S.5) by taking $G = F$:

$$\tilde{P}_F = \frac{1}{d_\Omega + 1} \left( P_F + P_{F\setminus \Omega} \right) = \frac{1}{d_\Omega + 1} \left( 1 + P_\Omega \right).$$

(S.8)

Inserting Eqs. (S.7) and (S.8) into Eq. (S.4), we obtain Eq. (3) in the main text.

As mentioned in the main text, the approximation

$$S_2[A] = -\langle \log(\text{Tr}_A \rho_A^2) \rangle \sim -\log(\langle \text{Tr}_A \rho_A^2 \rangle) = -\log P_A$$

(S.9)

gives a good estimate of the average entropy $S_2(A)$. The accuracy of this approximation is illustrated in Fig. S2(b), using as a model a 1D system in a random matrix product state, $|\psi\rangle = \sum_{s_1 \ldots s_k} \text{Tr} (A_1^{s_1} \cdots A_k^{s_k}) |s_1 \cdots s_k\rangle$, where $A_i^{s_i}$ are $N_b \times N_b$ random matrices sampled from the Gaussian unitary ensemble with local bond dimension $N_b$ [x axis in Fig. S2(b)]. Fig. S2(b) suggests that the annealed approximation remains accurate even for states with small bond dimension, producing an error as low as $\epsilon \sim 10^{-2}$ for $N_b \sim 1$.

**SECTION II: EVOLUTION OF HARTLEY ENTROPIES**

In this section, we derive the evolution Equations (10,11) for subsystem rank (whose logarithm is the Hartley entropy).

To study the evolution of the rank, it is convenient to use a tensor network representation of the system state. We divide the system into four subsets shown in Fig. S1(a) and associate with each subset a corresponding identically named tensor $A$ or $B$, $C$, or $D$, where indices $\alpha$, $\beta$, $\gamma$, and $\delta$ run over corresponding basis states of each subset of qudits. The structure of the tensors will depend on the dimensionality of the system and other properties of the circuit structure.

Let us start with a simple calculation for a 1D setting. For 1D systems, the tensor network is a matrix product state (MPS) representation of the system that can be written as

$$|\psi\rangle = \sum_{n_1 \ldots n_4, \alpha \beta \gamma \delta} A_{n_1 n_2}^{\alpha} B_{n_2 n_3}^{\beta} C_{n_3 n_4}^{\gamma} D_{n_4 n_1}^{\delta} |\alpha \beta \gamma \delta\rangle,$$

(S.10)
where indices $n_i = 1, \ldots, N_i$ run over the $N_i$ basis states of the bond connecting two of the subsystems, as shown in Fig. S1(b). Now consider a transformation $V$ supported on subsystem $\omega$ composed of $C$ and $D$. The MPS representation of the resulting state can be written as

$$V |\psi\rangle = \sum_{n,\alpha,\beta,\gamma} A_{n_1n_2}^\alpha B_{n_2n_3}^\beta C_{n_3n_4}^\gamma |\alpha\beta\gamma\rangle,$$

where $n'_4 = 1, \ldots, N'_4$ is expressed through the new bond dimension $N'_4$ between tensors $\tilde{C}$ and $\tilde{D}$, and the new MPS matrices $\tilde{C}$ and $\tilde{D}$ are connected to the initial ones by the relation

$$\sum_{n_4'} \tilde{C}_{n_3n_4}^{\gamma} \tilde{D}_{n_4' n_1}^{\delta} = \sum_{n_4, \gamma', \delta'} V_{\gamma\delta\gamma'\delta'} C_{n_3n_4}^{\gamma'} D_{n_4 n_1}^{\delta'}.$$

If $V$ is a unitary operator, this relation contains $n_s = N_1 N_3 d_{G\omega} d_{\omega G}$ equations. The matrix $\tilde{C}$ has $d_{\omega G} N_1 N'_4$ degrees of freedom (i.e indices), while the matrix $\tilde{D}$ has $d_{\omega G} N_2 N'_4$ degrees of freedom. Importantly, $N'_4$ of these indices are redundant due to the existence of a gauge transformation $\tilde{C}' = \tilde{C}M$ and $\tilde{D}' = M^{-1} \tilde{D}$ for any invertible $N'_4 \times N'_4$ matrix $M$. As a result, for the number of equations to coincide with the number of independent variables, the new rank $N'_4$ must satisfy

$$d_{G\omega} d_{\omega G} N_1 N_3 - d_{G\omega} N_1 N'_4 - d_{\omega G} N_2 N'_4 + N'_4^2 = 0.$$

This expression can be rewritten as $(N'_4 - d_{G\omega} N_3)(N'_4 - d_{\omega G} N_1) = 0$, an equation with two positive roots. One of the solutions can be used to compute the rank of the subset $G$,

$$R_G' = \text{rank}(B^\beta \tilde{C}^\gamma) = N_2 N'_4.$$

Taking into account that $R_{G\omega} = \text{rank}(B^\beta) = N_2 N_3$ and $R_{G\omega G} = \text{rank}(B^\beta C^\gamma D^\delta) = N_1 N_2$, we obtain

$$R_G' = \min(d_{G\omega} R_{G\omega}, d_{G\omega} R_{G\omega G}),$$

which is Eq. (10) in the main text. In the case when $d_{G\omega} = d_{\omega G} = q$ the formula simplifies to

$$R_G' = q \min(R_{G\omega}, R_{G\omega G}),$$

leading to the following expression for the Hartley entropy:

$$S_0[G] = \min(S_0[G \setminus \omega], S_0[G \cup \omega]) + \log q.$$

Consider now a measurement that projects the system onto state $|\psi\rangle = V |\psi\rangle / \sqrt{\langle \psi | V | \psi \rangle}$, where $V$ is supported on subset $\Omega$. We consider the same subdivision of the system up to the replacement $\omega \to \Omega$. Without loss of generality,
the transformation $V$ can be chosen to be a projector on a subset of $\Omega$ of the form $V = I_{AB} \otimes |00\rangle \langle 00|_{CD}$. Therefore, $B^2 = 0$ and $G^\gamma = 0$ for any $\beta, \gamma \neq 0$. The zeroth components of these tensors are connected to the initial MPS representation via

$$
\sum_{n_4} \tilde{C}^0_{n3n4} \tilde{D}^0_{n4n1} = \text{const} \times \sum_{n_4} C^0_{n3n4} D^0_{n4n1}, \tag{S.18}
$$

where the constant arises due to normalization.

Using analysis similar to the case of unitary $V$, we find that Eq. (S.18) contains $N_1 N_3$ equations for $N_3 N_4^t + N_1 N_4^t - N_4^{t2}$ variables. Hence, the new rank satisfies

$$
R'_G = \min(R_{G \setminus \Omega}, R_{G;\Omega}), \tag{S.19}
$$

which is Eq. (11) in the main text.

These results can be generalized to the more general (beyond 1D) tensor structure shown in Fig. S1(c). The MPS then contains four-index tensors capturing the most general structure of the state:

$$
|\psi\rangle = \sum_{n,\alpha,\beta,\gamma,\delta} A^\alpha_{nAB,\alpha AC,\alpha AD} B^\beta_{nAB,\beta BC,\beta BD} C^\gamma_{nAC,\gamma BD,\gamma CD} D^\delta_{nAD,\delta BD,\delta CD} |\alpha \beta \gamma \delta\rangle, \tag{S.20}
$$

where indices $n_{GG'} = 1, \ldots, N_{GG'}$ run through the $N_{GG'}$ basis state of the bond between sets $G$ and $G'$.

Similarly to the 1D case, we consider a transformation $V$ that affects subsystem $\omega$ and changes tensors $C$ and $D$. The new tensors are related to the original ones via

$$
\sum_{n_{CD}} \tilde{C}^\gamma_{nAC,\alpha BC,\alpha CD} \tilde{D}^\delta_{nAD,\gamma BD,\gamma CD} = \sum_{n_{CD},\beta,\gamma'} V_{\gamma \beta,\gamma' \alpha} C^\gamma'_{nAC,\beta BC,\beta CD} D^\delta'_{nAD,\gamma BD,\gamma CD}. \tag{S.21}
$$

Analysis similar to the 1D case applies here. Equation (S.21) contains $n_\gamma = d_{G \setminus \omega, d_{\omega \setminus G} N_{AC} N_{BC} N_{CD}}$ equations for the $d_{G \setminus \omega} N_{AC} N_{BC} N_{CD}^{t}$ variables in tensor $\tilde{C}$ and the $d_\omega G N_{AD} N_{BD} N_{CD}^{t}$ variables in tensor $\tilde{D}$. Excluding $N_{CD}^{t2}$ redundant variables, we find that $N_{CD}^{t}$ satisfies

$$
N_{CD}^{t2} - d_{G \setminus \omega} N_{AC} N_{BC} N_{CD}^{t} - d_\omega G N_{AD} N_{BD} N_{CD}^{t} + d_{G \setminus \omega} d_\omega G N_{AC} N_{BC} N_{AD} N_{BD} = 0, \tag{S.22}
$$

which can be rewritten as

$$
(N_{CD}^{t} - d_{G \setminus \omega} N_{AC} N_{BC})(N_{CD}^{t} - d_\omega G N_{AD} N_{BD}) = 0, \tag{S.23}
$$

which has two positive roots. Taking into account that

$$
R'_G = \text{rank}(B^\beta C^\gamma) = N_{AB} N_{BD} N_{AC} N_{CD}^{t}, \tag{S.24}
$$

and

$$
R_{G \setminus \omega} = \text{rank}(B^\beta) = N_{AB} N_{BC} N_{BD}, \quad R_{\omega \setminus G} = \text{rank}(B^\beta C^\gamma D^\delta) = \text{rank}(A^\alpha) = N_{AB} N_{AC} N_{AD}, \tag{S.25}
$$

and taking the smaller root in Eq. (S.23), we obtain the following equation for the rank:

$$
R'_G = \min(d_{G \setminus \omega} N_{AC}^{t2} R_{G \setminus \omega}, d_\omega G N_{BD}^{t2} R_{\omega \setminus G}). \tag{S.26}
$$

To express quantities such as $N_{AC}^{t2}$ and $N_{BD}^{t2}$, one needs expressions for the rank corresponding to other subsets of the system:

$$
R_{G \setminus \omega} = \text{rank}(C^\gamma) = N_{AC} N_{BC} N_{CD},
$$

$$
R_{\omega \setminus G} = \text{rank}(D^\delta) = N_{AD} N_{BD} N_{CD}, \tag{S.27}
$$

$$
R_{G \Delta \omega} = \text{rank}(A^\alpha C^\gamma) = \text{rank}(B^\beta D^\delta) = N_{AB} N_{AD} N_{BC} N_{CD}.
$$

It follows from these expressions that

$$
N_{BD}^{t2} = \frac{R_{G \setminus \omega} R_{\omega \setminus G}}{R_{G \Delta \omega}}, \quad N_{AC}^{t2} = \frac{R_{\omega \setminus G} R_{G \setminus \omega}}{R_{G \Delta \omega}}. \tag{S.28}
$$
Substituting these equalities into Eq. (S.26), we obtain the final expression connecting the rank of subspace $G$ after the application the unitary $V$ to ranks before the application:

$$R_G' = \frac{R_{G\cap \omega} R_{G\cap \omega}}{R_{G\cap \omega}} \min(d_{G\cap \omega} R_{G\cap \omega}, d_{\omega\setminus G} R_{\omega\setminus G}).$$  \hspace{1cm} (S.29)

A similar expression can be obtained for the effect of a measurement:

$$R_G' = \frac{R_{G\cap \Omega} R_{G\cap \Omega}}{R_{G\cap \Omega}} \min(R_{G\cap \Omega}, R_{\Omega\setminus G}),$$  \hspace{1cm} (S.30)

where, as before, $\Omega$ is the measured set.

In 1D systems, the evolution described by Eqs. (S.15) and (S.19) can be mapped to the minimum cut problem on a square lattice. To show this, we use the trajectory representation we defined for purities, but now formulated for ranks $R_G$. We formally write the evolution in the form

$$R_G' = \min_G (\mathcal{L}_{G,G'} R_{G'}),$$  \hspace{1cm} (S.31)

where the Liouvillian $\mathcal{L}$ has the same structure as for the evolution of physical purities $P$ given by Eq. (2) and the numerator of Eq. (3), with $c_\\cdot = d_{G\cap \omega}$ and $c_+ = d_{\omega\setminus G}$.

As for purities, we consider all possible trajectories $\mathcal{G} = \{G_1 \rightarrow G_2 \cdots \rightarrow G_n\}$ such that $G_{k+1} \in \mathcal{N}_k[G_k]$, and $G_1 = A$. Then, if the system is initialized in a product state, $R_G(0) = 1$, the evolution can be presented in the form

$$R_A = \min_{\mathcal{G}} R_{G'}, \quad R_G = \prod_{k=1}^{n} \mathcal{L}_{G_k,G_{k+1}}^{k}.$$  \hspace{1cm} (S.32)

The proof of this expression can be carried out by induction. First, the expression in Eq. (S.31) is equivalent to Eq. (S.32) under the condition that initially $R_G = 1$ for any $G$. Next, we assume that Eq. (S.32) holds for a circuit of depth $n - 1 \geq 2$ described by Liouvillians $\{\mathcal{L}_2, \ldots, \mathcal{L}_n\}$ and consider different $n$-step trajectories $\mathcal{G}[G']$ starting from the set $G'$. Then

$$R_A^{n+1} = \min_{G'} (\mathcal{L}_{G',G'}^{1} \prod_{G_k \in \mathcal{G}[G']} \mathcal{L}_{G_k,G_{k+1}}^{k}) = \min_{\mathcal{G}} R_{G'}.$$  \hspace{1cm} (S.33)

In the case of a 1D brickwork configuration, the rank can be expressed using the same statistical model as in Eq. (9),

$$R_A = \min_{\mathcal{G}} \exp(-\alpha E[\mathcal{G}]),$$  \hspace{1cm} (S.34)

where $\alpha = \log q$ and $E[\mathcal{G}]$ are the energies of all allowed configurations corresponding to $\mathcal{G}$ [see Eqs. (S.55)-(S.57)]. The minimum configuration energy for the statistical model is then given by the minimum total length of domain walls excluding all dashed segments on a percolated square lattice (see Sec. IV for more details). In the case of a bipartition, this reduces to a minimum path configuration connecting the cut at the top of the lattice to its other boundaries.

**SECTION III: HYDRODYNAMIC EQUATIONS FOR ENTROPIES IN 1D**

In this section, we derive the 1D KPZ equation for Rényi entropies [Eq. (5) in the main text] and its analytical solution [Eq. (6)], as well as the continuous evolution equation for Hartley entropies [Eq. (12)].

Let us start from the formal solution of Eq. (5). Substituting the definition of the entropy $S_2(t, x) = -\log P_c(t, x)$, we obtain a linear partial differential equation for the continuous approximation of the average purity $P_c(t, x)$ (subscript $c$ refers to the continuous approximation),

$$\partial_t P_c = \mu \partial^2_x P_c - \beta P_c, \quad P_c(t, x = 0) = P_c(t, x = N) = 1.$$  \hspace{1cm} (S.35)

For simplicity, we take a product initial state with $P_c(t = 0, x) = 1$. Substituting $P_c = 1 + \delta P_c$ we obtain

$$\partial_t \delta P_c = \mu \partial^2_x \delta P_c - \beta \delta P_c - \beta,$$  \hspace{1cm} (S.36)
with zero initial and boundary conditions $\delta P_e(t,0) = \delta P_e(t,N) = \delta P_e(0,x) = 0$. Equation (S.36) can be solved by the Fourier method. Expanding the solution in a Fourier series,

$$\delta P_e = \sum_{n=1}^{\infty} A_n(t) \sin (k_n x), \quad k_n = n\pi/N, \quad (S.37)$$

and expanding the constant term $\beta$ on the RHS of (S.36) in a Fourier series,

$$\beta = \sum_{n=1}^{\infty} \beta_n \sin k_n x, \quad \text{where} \quad \beta_n = \frac{2\beta}{N} \int_0^N \sin (k_n x) dx = \begin{cases} 0, & \text{if } n = 2m \\ \frac{4\beta}{\pi n}, & \text{if } n = 2m + 1 \end{cases}, \quad (S.38)$$

we obtain a set of ordinary differential equations for coefficients $A_n(t)$,

$$\dot{A}_n(t) = -(\beta + \mu)A_n(t) - \frac{4\beta}{\pi n} \delta_{n,\text{odd}}. \quad (S.39)$$

Here $\delta_{n,m}$ is the Kronecker delta function. The solution to (S.39) reads

$$A_n(t) = \begin{cases} A_n(0)e^{-(\beta+\mu k_n^2)t}, & \text{if } n = \text{even} \\ A_n(0)e^{-(\beta+\mu k_n^2)t} + \frac{4\beta}{k_n(\beta+\mu k_n^2)} \left(e^{-(\beta+\mu k_n^2)t} - 1\right), & \text{if } n = \text{odd} \end{cases}, \quad (S.40)$$

Finally, using the initial conditions $A_n(0) = 0$, we obtain the solutions

$$P_e(t,x) = 1 + \frac{4\beta}{N} \sum_{m=0}^{\infty} \left(e^{-(\beta+\mu k_{2m+1}^2)t} - 1\right) \frac{\sin (k_{2m+1} x)}{k_{2m+1}(\beta+\mu k_{2m+1}^2)}, \quad (S.41)$$

$$S_2(t,x) = -\log (P_e(t,x)). \quad (S.42)$$

As $t \to \infty$, the exponent in (S.41) vanishes. The corresponding stationary purity (i.e. at $t \to \infty$) obeys the following equation:

$$\mu \partial_{xx} P - \beta P = 0. \quad (S.43)$$

The solution of Eq. (S.43) with the boundary conditions in Eq. (S.35) reads

$$P_e(t \to \infty, x) = \frac{\cosh (\alpha (x - N/2))}{\cosh (\alpha N/2)}, \quad (S.44)$$

where $\alpha = \sqrt{\beta/\mu}$. Equation (S.44) also follows directly from Eq. (S.41). The asymptotic value of the entropy at $x = N/2$ read:

$$S_2(t \to \infty, x = N/2) = \log \cosh (\alpha N/2). \quad (S.45)$$

In the thermodynamic limit ($N \to \infty$), we obtain volume-law growth of the entropy $S_2(t \to \infty, x = N/2) = \alpha N/2 - \log 2 + O(\exp(-\alpha N))$.

We now derive parameters $\beta$ and $\mu$ in the continuous Equation (5) from the underlying discrete evolution. To find parameter $\beta$, we consider a homogeneous solution of the discrete model, $P_x(t) = P_{x+1}(t)$. In this case, after a single time step, one has $P_x(t+1) = 2cP_x(t)$. Similarly, for the entropy evolution, $S_2(t+1, x) = S_2(t, x) + \beta$. Taking $S_2(t, x) \approx -\log P_e(t, x)$ and comparing these two expressions, we find

$$\beta = -\log (2c) = \log \left(\frac{q^2 + 1}{q}\right). \quad (S.46)$$

To find the diffusion coefficient $\mu$, we consider a stationary solution $P_x(t) = P_x(t+1)$. Let us use the following ansatz for the solution to the discrete equation: $P_{x+1}(t) = \gamma P_x(t)$. Then the condition of time-invariance leads us to

$$P_x(t+1) = P_x(t) = c \left(\frac{1}{\gamma} + \gamma\right) P_x(t). \quad (S.47)$$
This condition is satisfied if
\[
\gamma = \frac{1}{2e} \left(1 \pm \sqrt{1 - 4c^2}\right) \in \{q,q^{-1}\},
\]
which corresponds to positive and negative slopes for the Rényi entropy of the first and second halves of the chain, respectively.

Assuming continuity of the entropy, we find that
\[
\frac{\partial S_2}{\partial x} \simeq S_2(t, x + 1) - S_2(t, x) = \sqrt{\frac{\beta}{\mu}} = \log q.
\]
This finally leads to the expression
\[
\mu = \frac{\log [(q^2 + 1)/2q]}{(\log q)^2}.
\]
For \(q = 2\), this gives \(\mu \approx 0.464\), close to the phenomenological value \(\mu = 1/2\) considered in Ref. [9]. In the limit \(q \to \infty\), the diffusion coefficient vanishes as \(\mu \sim 1/\log q\).

**Derivation of Eq. (12):** Using the expression for the evolution of the Hartley entropy under unitary gates, \(S_0(t + 1, x) = \min|S_0(t, x - 1), S_0(t, x + 1)| + \log q\), and using identities \(\min(a, b) = a + \min(b - a, 0)\) and \(\min(a, 0) = a/2\), we find that
\[
\partial_t S_0 \simeq S_0(t + 1, x) - S_0(t, x) \simeq \frac{|S_0(t, x + 1) - S_0(t, x - 1) - |S_0(t, x + 1) - S_0(t, x - 1)||}{2} + S_0(t, x - 1) - S_0(t, x) + \log q \simeq -|\partial_x S_0| + \frac{1}{2} \partial^2_x S_0 + \log q,
\]
which results in Eq. (12). In deriving (S.51), we used approximations \([S_0(t, x + 1) - S_0(t, x - 1)]/2 \simeq \partial_x S_0\) and \(S_0(t, x + 1) - S_0(t, x) \simeq \partial_x \tilde{S}_0 + \frac{1}{2} \partial^2_x S_0\).

**Solution of the hydrodynamic Equation (12) for \(S_0\) in 1D:** In the case of a product initial state, the initial condition for the Hartley entropy in 1D is \(S_0(t = 0, x) = 0\). It is easy to see by direct substitution that the solution of the hydrodynamic equation for the Hartley entropy (see Eq. (12) and Table I) reads:
\[
\frac{S_0(t, x)}{\log q} = \begin{cases} 
  x, & \text{if } 0 \leq x \leq t, \\
  t, & \text{if } t \leq x \leq N - t, \\
  t - x, & \text{if } N - t \leq x \leq N.
\end{cases}
\]
Moreover, within each segment defined in Eq. (S.52), the second derivative \(\partial^2_x S_0\) vanishes, except for special points where the second derivative is discontinuous. Therefore, in the special case when the initial state is a product state, the hydrodynamic equation for the Hartley entropy reduces to
\[
\partial_t \tilde{S}_0 = 1 - |\partial_x \tilde{S}_0|,
\]
where \(\tilde{S}_0 = S_0/\log q\).

On the other hand, we can write the hydrodynamic KPZ equation for the Rényi entropy \(\tilde{S}_2 = S_2/\log q\) in the scaling limit \(q \to \infty\):
\[
\partial_t \tilde{S}_2 \simeq -(\partial_x \tilde{S}_2)^2 + 1,
\]
where we used the asymptotic values for the coefficients \(\beta = \log((q^2 + 1)/2q) \to \log q\) and \(\mu = \beta/(\log q)^2 \to 1/\log q\) at \(q \to \infty\). Note that the piecewise solutions with slopes 0, ±1 shown in in Eq. (S.52) satisfy both partial differential equations, Eq. (S.53) and Eq. (S.54). This analysis agrees with the statement made in the main text based on the Ising-model analogy: in the limit \(q \to \infty\), Rényi and Hartley entropies coincide, i.e. \(S_0(t, x) \to S_2(t, x)\), provided that the initial state is a product state, i.e. \(S_0(0, x) = S_2(0, x) = 0\).

In Fig. S3, we compare the dynamics of second Rényi and Hartley entropies in 1D by solving discrete (exact) and hydrodynamic (approximate) evolution equations listed in Table I. In Fig. S3(a,b), one can see that the hydrodynamic evolution (dashed lines) agrees well with the exact solution (solid lines). At asymptotically large times, the stationary solutions for \(s_0 = S_0/N\) and \(s_2 = S_2/N\) have the same shape. In Fig. S3(c), we plot the values of the entropy in the middle of the 1D chain, \(x = N/2\), for increasing values of the qudit dimension \(q\). The plot shows that, in the asymptotic limit \(q \to \infty\), the second Rényi entropy approaches the Hartley entropy, \(s_0(t, x) \to s_2(t, x)\).
FIG. S3. (a,b) Evolution of second Rényi and Hartley entropies in 1D under a brickwork Haar-random unitary circuit: comparison of discrete-time evolution and the solutions of the corresponding continuous-time hydrodynamic equations (equations are shown in Table I). Here we plot the specific entropy (entropy per qudit) $s_{0,2} = S_{0,2}/N$ for $q = 2$. The continuous-time equations were solved by a finite-difference scheme with a time-step $dt = 10^{-2}$. We chose an initial state where the two halves of the 1D system are disentangled from each other but each is in a maximally entangled state. (c) Second Rényi and Hartley entropies are shown in Table I. Here we plot the specific entropy (entropy per qudit) $s_{0,2} = S_{0,2}/N$ for $q = 2$. The continuous-time equations were solved by a finite-difference scheme with a time-step $dt = 10^{-2}$. We chose an initial state where the two halves of the 1D system are disentangled from each other but each is in a maximally entangled state. (c) Second Rényi and Hartley entropies are shown in Table I.

TABLE I. Discrete-time and continuous-time evolution equations for the second Rényi entropy and for the Hartley entropy.

| | Rényi entropy $S_2$ | Hartley entropy $S_0$ |
|---|---|---|
| Discrete-time evolution | $P_{x,t} = \frac{q}{q^2 + 1} \left( P_{x-1,t} + P_{x+1,t} \right)$, $S_{2,x,t}^{t+1} = -\log P_{x,t}^{t+1}$ | $S_{0,x,t}^{t+1} = \min \left( S_{0,x-1,t}^{t}, S_{0,x+1,t}^{t} \right) + \log q$ |
| Hydrodynamic evolution | $\partial_t S_2 = \mu \left( \partial_x^2 S_2 - (\partial_x S_2)^2 \right) + \beta$ | $\partial_t S_0 = \frac{1}{2} \partial_x^2 S_0 - |\partial_x S_0| + \log q$ |

SECTION IV: MAPPING TO A CLASSICAL MODEL IN 1D

In this section, we derive the classical Hamiltonian $H$ and the projector $P$ in Eqs. (8,9) in the main text.

We consider combined circuit layers each consisting of a single unitary layer and a single measurement layer in reverse chronological order. This combined circuit can be mapped to a collection of trajectories $\mathcal{G} = \{ G_1 \to G_2 \to \cdots \to G_n \}$ as described in the main text, where the Liouvillian $\mathcal{L}^{nm}$ for a single combined layer connects set $G_k$ to $G_{k+1}$, and each trajectory contributes to the purity according to Eq. (7). Our goal is now to map each trajectory to a classical state on a lattice with dynamical variables attached to the center of each lattice cell and to edges associated with measurements. At the end of this section, we cover open boundary conditions.

As a toy illustrative example, let us focus on a primitive circuit containing only two qudits, labeled $\Omega_1$ and $\Omega_2$, and a single combined unitary-measurement layer applied to them [see top of Fig. S4(a)]. This primitive system corresponds to a simple lattice with only three vertices and two edges shown inside a blue rectangle at the bottom of Fig. S4(a). Therefore, our proposed classical model has three lattice cell variables $(Z_1, Z_2, Z_3)$ and two edge variables $(J_{13}$ and $J_{23})$ [see labels in Fig. S4(b)]. To study the mapping of trajectory $\{ G_1 \to G_2 \}$ to a classical state on a lattice, we recall the trajectory defined in Fig. 1(b) of the main text, where each unitary and measurement layer is treated separately. Our single-step trajectory $\{ G_1 \to G_2 \}$ thus corresponds to a two-step trajectory $\{ G_1 \to G_2 \to G_3 \}$ in the language of Fig. 1(b). For both trajectories, the starting configuration is $G_1 = G_1' = A$. Notably, as we will see below, the final state for any trajectory is either $G_2' = G_3 = F$ (full system) or $\emptyset$, regardless of measurement locations.

Let us start from the case of a unitary circuit without measurements. Such a circuit can be described by six possible trajectories including all possible initial states $A$, as shown below in the first column of Eq. (S.55). These trajectories can be mapped to the classical spin configurations shown in the second column of Eq. (S.55). The contribution $P_{n}$ of
FIG. S4. Correspondence between trajectories $\mathcal{G}$ and configurations of a dynamical square lattice. (a) Top: two-qudit trajectory $\mathcal{G} = \{G_1 \rightarrow G_2 \rightarrow G_3\} = \{0 \rightarrow \Omega_1 \rightarrow F\}$ illustrated by blue and white cells reflecting, respectively, whether the qudit belongs to $G_4$ or not. The monitored circuit generating such a trajectory is shown on the right (the black dot is a single-qudit measurement, while the green rectangle is a two-qudit gate). Bottom: the blue rectangle marks the portion of the square lattice corresponding to the single-qudit measurement, while the green rectangle is a two-qudit gate. (b-d) Illustration of the correspondence between trajectories (on the background) and lattice configurations (b) in the absence of measurements, (c) with a measurement of one edge if the cell keeps its color in $G$ trajectory, and (d) with measurements of both qudits. The examples of prohibited lattice configurations are shown at the bottom; these configurations are projected out using operator $P$.

Each trajectory $\mathcal{G}$ to the purity in Eq. (7) is given in the third column in the form of the configuration energy $E[\mathcal{G}]$:

| Trajectory $\mathcal{G}$ | Classical configuration | $E[\mathcal{G}]$ |
|--------------------------|------------------------|-----------------|
| $\{0 \rightarrow 0 \rightarrow 0\}$, | $\{Z_1 = -1, Z_2 = -1, Z_3 = -1, J_{13} = 1, J_{23} = 1\}$ | 0 |
| $\{\Omega_1 \rightarrow \Omega_1 \rightarrow 0\}$, | $\{Z_1 = +1, Z_2 = -1, Z_3 = -1, J_{13} = 1, J_{23} = 1\}$ | 1 |
| $\{\Omega_1 \rightarrow \Omega_1 \rightarrow F\}$, | $\{Z_1 = +1, Z_2 = -1, Z_3 = +1, J_{13} = 1, J_{23} = 1\}$ | 1 |
| $\{\Omega_2 \rightarrow \Omega_2 \rightarrow 0\}$, | $\{Z_1 = -1, Z_2 = +1, Z_3 = -1, J_{13} = 1, J_{23} = 1\}$ | 1 |
| $\{\Omega_2 \rightarrow \Omega_2 \rightarrow F\}$, | $\{Z_1 = -1, Z_2 = +1, Z_3 = +1, J_{13} = 1, J_{23} = 1\}$ | 1 |
| $\{F \rightarrow F \rightarrow F\}$, | $\{Z_1 = +1, Z_2 = +1, Z_3 = +1, J_{13} = 1, J_{23} = 1\}$ | 0 |

For illustration purposes, the first two trajectories in Eq. (S.55) are shown as the top two diagrams in Fig. S4(b). There, as in Fig. 1(b) in the main text, we mark qudits that belong to $G_4$ as blue and the rest of the qudits as white. For unitary circuits, the edges are not treated as dynamical variables; instead, the edges are all taken to be numbers equal to unity, i.e. $J_{ij} = +1$. Also, no trajectory is mapped to the configurations $\{Z_1 = +1, Z_2 = +1, Z_3 = -1, J_{13} = 1, J_{23} = 1\}$ and $\{Z_1 = -1, Z_2 = -1, Z_3 = +1, J_{13} = 1, J_{23} = 1\}$; therefore, these configurations must be projected out using the operator $P$. We show the first of these prohibited configurations at the bottom of Fig. S4(b). Each allowed configuration contributes with energy $E[\mathcal{G}] = 1$ equal to the total length of domain walls (i.e. the number of red edges).

Now let us assume that a measurement is applied to one of the qudits $\Omega_k$, where $k = 1$ or $k = 2$, while the other qudit $\Omega_{k'}$ remains unmeasured (here we define $\Omega = 2$ and $\Omega = 1$). The measurement adds more accessible trajectories to the ones already listed in Eq. (S.55). Here are these additional trajectories, the corresponding classical configurations,
and the corresponding energies:

| Trajectory $\mathcal{G}$ | Classical configuration | $E[\mathcal{G}] = -\log(P_{\mathcal{G}})/\beta$ |
|---------------------------|-------------------------|-----------------------------------------------|
| $\{\emptyset \rightarrow \Omega_k \rightarrow \emptyset\}$, | $\{Z_k = -1, Z_\overline{k} = -1, Z_3 = -1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ | 1 |
| $\{\emptyset \rightarrow \Omega_k \rightarrow F\}$, | $\{Z_k = -1, Z_\overline{k} = -1, Z_3 = +1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ | 1 |
| $\{\Omega_k \rightarrow \emptyset \rightarrow \emptyset\}$, | $\{Z_k = +1, Z_\overline{k} = -1, Z_3 = -1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ | 0 |
| $\{\Omega_k \rightarrow F \rightarrow F\}$, | $\{Z_k = -1, Z_\overline{k} = +1, Z_3 = +1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ | 0 |
| $\{F \rightarrow \Omega_k \rightarrow F\}$, | $\{Z_k = +1, Z_\overline{k} = +1, Z_3 = +1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ | 1 |
| $\{F \rightarrow \Omega_k \rightarrow \emptyset\}$, | $\{Z_k = +1, Z_\overline{k} = +1, Z_3 = -1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ | 1 |

Trajectories 2 and 3 are shown as the top two diagrams in Fig. S4(c) for $k = 1$ (and $\overline{k} = 2$). As for the unitary case, $J_{k3} = 1$; however, since we measured $\Omega_k$, $J_{k3}$ is now a dynamical variable. Since no trajectories correspond to configurations $\{Z_1 = -1, Z_2 = +1, Z_3 = -1, J_{k3} = -1, J_{\overline{k}3} = 1\}$ and $\{Z_1 = +1, Z_2 = -1, Z_3 = +1, J_{k3} = -1, J_{\overline{k}3} = 1\}$, these configurations must be projected out by $P$. The first of these two prohibited configurations is shown at the bottom of Fig. S4(c).

Finally, if both qudits are measured, the following trajectories become accessible, in addition to those already listed in Eq. (S.55) and Eq. (S.56):

| Trajectory $\mathcal{G}$ | Classical configurations | $E[\mathcal{G}] = -\log(P_{\mathcal{G}})/\beta$ |
|---------------------------|-------------------------|-----------------------------------------------|
| $\{\emptyset \rightarrow F \rightarrow F\}$, | $\{Z_1 = -1, Z_2 = -1, Z_3 = +1, J_{13} = -1, J_{23} = -1\}$ | 0 |
| $\{\Omega_1 \rightarrow \Omega_2 \rightarrow \emptyset\}$, | $\{Z_1 = +1, Z_2 = -1, Z_3 = -1, J_{13} = -1, J_{23} = -1\}$ | 1 |
| $\{\Omega_1 \rightarrow \Omega_2 \rightarrow F\}$, | $\{Z_1 = +1, Z_2 = -1, Z_3 = +1, J_{13} = -1, J_{23} = -1\}$ | 1 |
| $\{\Omega_2 \rightarrow \Omega_1 \rightarrow \emptyset\}$, | $\{Z_1 = -1, Z_2 = +1, Z_3 = -1, J_{13} = -1, J_{23} = -1\}$ | 1 |
| $\{\Omega_2 \rightarrow \Omega_1 \rightarrow F\}$, | $\{Z_1 = -1, Z_2 = +1, Z_3 = +1, J_{13} = -1, J_{23} = -1\}$ | 1 |
| $\{F \rightarrow \emptyset \rightarrow \emptyset\}$, | $\{Z_1 = +1, Z_2 = +1, Z_3 = -1, J_{13} = -1, J_{23} = -1\}$ | 0 |

Trajectories 1 and 3 are shown as the top two diagrams in Fig. S4(d). Since no trajectories map to configurations $\{Z_1 = +1, Z_2 = +1, Z_3 = -1, J_{k3} = -1\}$ and $\{Z_1 = -1, Z_2 = -1, Z_3 = -1, J_{k3} = -1, J_{\overline{k}3} = -1\}$, these configurations must be projected out by $P$. Both prohibited configurations correspond to the “lambda”-configuration of dashed lines shown at the bottom of Fig. S4(d).

Using Eqs. (S.55), (S.56), and (S.57), it is straightforward to verify that the energy of each allowed configuration is described by the Ising-type interaction,

$$E[\mathcal{G}] = 1 - \frac{1}{2}(J_{13}Z_1Z_3 + J_{23}Z_2Z_3),$$

(S.58)

while all prohibited configurations satisfy

$$\frac{1}{4}(Z_3 - J_{13}Z_1)(Z_3 - J_{23}Z_2) = 1.$$ 

(S.59)

Therefore, the purity of set $A$ is given by

$$\hat{P}_A = \text{Tr} \left( P \exp(-\beta H) \right), \quad H = 1 - \frac{1}{4} \sum_{i,j} J_{ij}Z_iZ_j,$$

(S.60)

where the projector $P$ excludes prohibited configurations as well as sets the initial conditions for trajectory $\mathcal{G}$:

$$P = P_A \left( 1 - \frac{1}{4}(Z_3 - J_{13}Z_1)(Z_3 - J_{23}Z_2) \right),$$

(S.61)

where $P_A = \frac{1}{4} \prod_{i \in A} (1 - Z_i) \prod_{j \in F \setminus A} (1 + Z_j)$, where products are taken over the $Z$-variables at the top of the lattice (i.e. $Z_1$ and $Z_2$).

Having considered the case of two qudits and one layer, we can generalize the result to an arbitrary number of qudits and layers. This generalization is possible because: (a) the process is Markovian, so contributions from different layers do not interfere; (b) gates in the same layer do not overlap, so their contributions are also independent. Therefore, the
prohibited:
\[ \sum b \]

**FIG. S5.** **Boundary conditions.** Open boundaries put additional constraints on the allowed spin-model configurations. Edge pairs of squares (green boxes) cannot exhibit configurations shown on the right, i.e. solid red and dashed black edges are prohibited in the indicated locations independently of square colors.

The full multi-qudit multi-layer configuration on a square lattice is obtained by gluing together 2-qudit 1-layer elements described above, while the effective energy of this full configuration is just the sum of the energies of these elements:

\[
H = \frac{N_0}{2} - \frac{1}{4} \sum_{(i,j)} J_{ij} Z_i Z_j, \quad \mathcal{P} = \mathcal{P}_A \prod_{(i,j,k) \in \Sigma_3} \left( 1 - \frac{1}{4}(Z_k - J_{ik} Z_i)(Z_k - J_{jk} Z_j) \right),
\]

which is Eq. (8) in the main text.

Another approach to dealing with prohibited configurations (without projecting them out) is to consider a modified Ising Hamiltonian with a penalty term:

\[
\tilde{P}_A = \lim_{\Gamma \to \infty} \text{Tr} \mathcal{P}_A \exp(-\beta H_\Gamma),
\]

where

\[
H_\Gamma = \frac{1}{2} N_0 - \frac{1}{4} \sum_{(i,j)} J_{ij} Z_i Z_j + \Gamma \sum_{(i,j,k) \in \Sigma_3} (Z_k - J_{ik} Z_i)(Z_k - J_{jk} Z_j).
\]

In the limit of infinite penalty coefficient \( \Gamma \), the two approaches are equivalent.

One can compute the energies of domain-wall configurations without explicitly using the Hamiltonian. For unitary evolution, all Ising couplings are \( J_{ij} = 1 \); therefore, the energy of any allowed Ising configuration \( E[\mathcal{G}] \) is equal to the total length of domain walls. In the presence of measurements, \( E[\mathcal{G}] \) is equal to the total length of solid segments of domain walls (i.e. solid red edges) plus the total number of dashed edges outside of the domain walls (i.e. dashed black edges). The projector \( \mathcal{P} \) prohibits configurations shown in Fig. 1(c). Because dashed edges resemble cuts on a lattice, we can draw an analogy of the model to trajectories on a *dynamical* percolated lattice.

**Boundary conditions.** Boundaries result in the presence of unpaired qudits/cells at the edges that are not affected by the unitaries at even (or odd, depending on where exactly the boundary is) layers, as can be seen from Fig. 1(a). These qudits exhibit additional prohibited trajectories at even (or odd) times. Specifically, black dashed and solid red lines are prohibited in the locations shown in Fig. S5. Such trajectories can be projected out by taking \( \mathcal{P} \to \mathcal{P} \prod_{ij \in \Sigma_b} \frac{1}{2}(1 + J_{ij} Z_i Z_j) \) for all boundary square pairs \( \Sigma_b \) highlighted as green boxes in Fig. S5.

**SECTION V: CONTINUOUS EVOLUTION**

In this section, we show how continuous evolution of the system under a stochastic Hamiltonian and local continuous measurements gives rise to Eqs. (14) and (15) in the main text. We also analyze the accuracy of the mean-field approximation used to simplify Eq. (15). Finally, we show that the continuous evolution in Eqs. (14,15) can be used to derive the discrete evolution in Eqs. (2,3).

First, we prove that the eigenbasis of the monitored operators can be randomized while preserving purities. This randomization will allow us to derive a differential equation for the purities. More specifically, we consider random time-dependent unitaries \( U_{\tau,i}^\dagger(t) \) supported on a single qudit \( i \) and drawn from the circular unitary ensemble. In order to have a time-continuous description, we assume that the matrices are weakly correlated in time, \( \langle [U_{\tau,i}(t)]_{\mu\nu}[U_{\tau,j}(t')]_{\mu'\nu'} \rangle = q^{-1} \delta_{\mu\mu'} \delta_{\nu\nu'} \delta_{ij} f[(t - t')/\tau] \), where \( f[x] \) is a smooth correlation function satisfying \( f[0] = 1 \) and \( \lim_{|x| \to \infty} f[x] = 0 \). The correlation \( f[x] \) will be later removed by taking the limit \( \tau \to 0 \). In this limit, the
unitaries represent a stochastic process where, at each time, the matrix \( U_{\tau=0,i}(t) \) is drawn independently from the circular unitary ensemble.

Consider the unitary \( U_{\tau}(t) = \prod_i U_{\tau,i}(t) \) and the corresponding rotating-frame wavefunction

\[
|\psi'(t)\rangle = U_{\tau}^\dagger(t)|\psi(t)\rangle.
\]

Since \( U_{\tau,i}(t) \) are defined as single-qudit unitary operators, the purity \( P_G \) for any \( G \) remains invariant under this transformation:

\[
P_G(|\psi'\rangle\langle\psi'|) = P_G(|\psi\rangle\langle\psi|).
\]

The new wavefunction \( |\psi'(t)\rangle \) satisfies

\[
\frac{d}{dt} |\psi'\rangle = -i \left( H'(t) + H_U(t) \right) |\psi'\rangle + \left[ -\sum_j \kappa_j \left( O_j(t) - \langle \psi' | O_j(t) | \psi' \rangle \right)^2 + \sum_j \xi_j(t) \sqrt{2\kappa_j} \left( O_j(t) - \langle \psi' | O_j(t) | \psi' \rangle \right) \right] |\psi'\rangle,
\]

where

\[
H_U(t) \equiv \sum_i U_{\tau,i}^\dagger(t) \partial_t U_{\tau,i}(t),
\]

\[
H'(t) \equiv U_{\tau,i}^\dagger(t) H(t) U_{\tau,i}(t) = \sum_i I_{F \setminus \omega_i} \otimes h_i'(t),
\]

\[
O_j(t) \equiv U_{\tau,j}^\dagger(t) O_j U_{\tau,j}(t). \tag{S.70}
\]

The modified stochastic Hamiltonians \( h_i'(t) \equiv U_{\tau,i}^\dagger(t) h_i(t) U_{\tau,i}(t) \) have the same distribution as \( h_i(t) \), due to the invariance of the Gaussian unitary ensemble under unitary rotations. The new Hamiltonian term \( H_U(t) \) is a sum of single-qudit operators. Therefore, the rotation in Eq. (S.65) effectively randomizes the measurement bases: \( O_j \to U_{\tau,j}^\dagger(t) O_j U_{\tau,j}(t) \). The penalty for this is the addition of single-qudit terms to the Hamiltonian, but with no effect on the distribution of the original stochastic Hamiltonian terms. Importantly, we show below that the additional single-qudit terms do not affect (averaged) purities \( P_G \).

**Unitary dynamics.** Let us first focus on the effect of the combined Hamiltonian

\[
H_c(t) = H_U(t) + \sum_i H_i'(t),
\]

where each local stochastic term can be represented as \( H_i'(t) = \sum_{\omega_i} \otimes h_i'(t) \), where \( h_i'(t) \) are independent random matrices supported on sets \( \omega_i \) as introduced in the main text. The unitary evolution operator for infinitesimal time \( dt \) is

\[
U_{t,dt} = \mathcal{T} \exp \left( -i \int_t^{t+dt} dt' H_c(t') \right). \tag{S.72}
\]

Therefore, the evolution of the density matrix satisfies

\[
\rho(t + dt) = U_{t,dt} \rho U_{t,dt}^\dagger = \rho(t) - i \int_t^{t+dt} [H_U(t'), \rho] \, dt' - i \sum_i \int_t^{t+dt} [H_i'(t'), \rho] \, dt' - \frac{1}{2} \sum_{ij} \int_t^{t+dt} \, dt' \int_t^{t+dt} \, dt'' [H_i'(t'), [H_j'(t''), \rho]] + O(dt^2). \tag{S.73}
\]

The evolution of purity is connected to the density matrix \( \rho = |\psi'\rangle\langle\psi'| \) as follows:

\[
\frac{d}{dt} P_G = \frac{d}{dt} \langle \text{Tr}_G \rho_G^2 \rangle = \lim_{dt \to 0} \langle \text{Tr}_G \frac{\rho_G^2(t + dt) - \rho_G^2(t)}{dt} \rangle_{\text{circ}, H_c'(t)}. \tag{S.74}
\]

The averaging in Eq. (S.74) includes both the circuit average \( \langle \ldots \rangle_{\text{circ}} \) over different evolution histories realized by the stochastic Hamiltonian \( H_c' \) prior to time \( t \) and the average \( \langle \ldots \rangle_{H_c'(t)} \) over the stochastic Hamiltonian \( H_c' \) at the current time \( t \). At this point, we are not yet averaging over \( U_{\tau,ij} \).
To calculate the quantity on the RHS of Eq. (S.74), we use the reduction
\[
\langle H'_i(t)O H'_j(t') \rangle_{H_i} = \frac{1}{2} \alpha_i \delta_{ij} \delta(t-t')(W_i O W_i)_W ,
\]  
where \( O \) is any operator and \( W_i \) is a Wigner random matrix from a Gaussian unitary ensemble supported on \( \omega_i \) and satisfying
\[
\langle W_{a,i} W_{a',i'}^{*} W_{b,j} W_{b',j'}^{*} \rangle_{W} = \frac{1}{d_{\omega}} \delta_{aa'} \delta_{bb'} \delta_{ii'} \delta_{jj'} .
\]  
Since \( \langle H'_i(t) \rangle_{H_i} = 0 \), Eq. (S.74) takes the form
\[
\frac{d}{dt} P_G = -i \operatorname{Tr}_G \left( \left\{ \operatorname{Tr}_{F \setminus G}[H_U, \rho], \rho_G \right\} \right) - \frac{\alpha_i}{2} \left\langle \left( \operatorname{Tr}_G \left( \left[ \operatorname{Tr}_{F \setminus G}[W_i, \rho] \right]^2 \right) + \operatorname{Tr}_G \left( \left[ \operatorname{Tr}_{F \setminus G}[W_i, \rho] \right]^2 \right) \right\} \right\rangle_{\text{circ}, W} .
\]  
\[
= -\frac{\alpha_i}{2} \left\langle \left( \operatorname{Tr}_G \left( \left[ \operatorname{Tr}_{F \setminus G}[W_i \rho] \operatorname{Tr}_{F \setminus G}[W_i \rho] \right] + \operatorname{Tr}_G \left( \left[ \operatorname{Tr}_{F \setminus G}[W_i \rho] \operatorname{Tr}_{F \setminus G}[W_i \rho] \right] - 2 \operatorname{Tr}_G \left( \left[ \operatorname{Tr}_{F \setminus G}[W_i \rho] \operatorname{Tr}_{F \setminus G}[W_i \rho] \right] \right) \right) \right\} \right\rangle_{\text{circ}, W} .
\]  
(S.77)

The first term in (S.77) that contains \( H_U \) vanishes since it acts on single qudits.

Averages in Eq. (S.77) can be calculated using the following identities:
\[
\left\langle \operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[W \rho]^2 \right) \right\rangle_W = \left\langle \operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[\rho W] \right) \right\rangle_W = \frac{1}{d_{\omega}} \operatorname{Tr}_G \left( \rho_G \left( H_\omega \right) \right) ,
\]
\[
\left\langle \operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[W \rho W] \right) \right\rangle_W = \left\langle \operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[W \rho W] \right) \right\rangle_W = \operatorname{Tr}_G \left( \rho_G^2 \right) ,
\]
\[
\left\langle \operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[W \rho W] \right) \right\rangle_W = \frac{1}{d_{G \setminus \omega}} \operatorname{Tr}_G \left( \rho_G^2 \left( H_{G \setminus \omega} \right) \right) .
\]  
(S.78)

Combining equations (S.77) and (S.78), we obtain
\[
\frac{d}{dt} P_G = - \sum_i \alpha_i \left( P_G + \frac{P_G \delta_{i \omega}}{d_{\omega}} - \frac{P_G}{d_{i \setminus G}} - \frac{P_G}{d_{\omega \setminus i}} \right) ,
\]  
(S.79)

which is Eq. (14) in the main text.

**Continuous monitoring.** Let us consider now the dynamics of the system under continuous measurements of observables \( O_j(t) \) applied to qudits \( \Omega_j \) in the randomized basis, \( O_j(t) = U_{r,j}(t) O_j U_{r,j}^\dagger(t) \):
\[
\frac{d}{dt} \langle \psi_i(t) \rangle = - \sum_j \kappa_j \left( O_j(t) - \langle \psi_i | O_j(t) | \psi_i \rangle \right)^2 + \sum_j \xi_j(t) \sqrt{2} \kappa_j \left( O_j(t) - \langle \psi_i | O_j(t) | \psi_i \rangle \right) \right| \psi_i \rangle .
\]  
(S.80)

Here coefficients \( \kappa_j \) characterize the strength of the coupling to the measurement apparatus, and \( \xi_j(t) \) are independent unbiased Gaussian random variables satisfying \( \langle \xi_i(t) \xi_j(t') \rangle_{\xi} = \delta_{ij} \delta(t-t') \). The average \( \langle \ldots \rangle_{\xi} \) over the random variables \( \xi \) amounts to averaging over the measurement back-action in the realization of the monitoring. We find that, upon averaging over \( \xi \), the purities evolve as
\[
\frac{d}{dt} P_G = 2 \sum_j \kappa_j \left\langle \operatorname{Tr}_G [\rho_G, O_j(t)] \right\rangle_{\text{circ}} + 2 \sum_j \kappa_j \left\langle \operatorname{Tr}_G \left( \left[ \operatorname{Tr}_{F \setminus G}[\{O_j(t), \rho\} - 2 \operatorname{Tr}(\rho O_j(t) \rho) \} \right] \right) \right\rangle_{\text{circ}} ,
\]  
(S.81)

where, as defined above, the circuit average \( \langle \ldots \rangle_{\text{circ}} \) is over the stochastic Hamiltonian \( H'_i \) prior to time \( t \).

Equation (S.81) can now be rewritten using the following identities (to ease notation, we suppress time dependence of \( O_j \)):
\[
\operatorname{Tr}_G [\rho_G, O_j^2] = -2 \left( \operatorname{Tr}_G [\rho_G O_j^2] - \operatorname{Tr}_G (\rho_G O_j)^2 \right) \delta_{\Omega_j \in G} ,
\]
\[
\operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[\rho, O_j] \right)^2 = 2 \left( \operatorname{Tr}_G (\rho_G^2 O_j^2) + \operatorname{Tr}_G (\rho_G O_j)^2 \right) \delta_{\Omega_j \in G} + 4 \operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}(\rho O_j)^2 \right) \delta_{\Omega_j \in F \setminus G} ,
\]
\[
\operatorname{Tr}_G \left( \operatorname{Tr}_{F \setminus G}[\{\rho, O_j\}] \right) \rho_G = 2 \operatorname{Tr}_G (\rho_G^2 O_j^2) \delta_{\Omega_j \in G} + 2 \operatorname{Tr}_L \left( \operatorname{Tr}_{F \setminus G}(\rho O_j) \rho_G \right) \delta_{\Omega_j \in F \setminus G} .
\]  
(S.82)
where \( \delta_{\Omega \in G} = 1 \) if \( \Omega \in G \) and \( \delta_{\Omega \notin G} = 0 \) otherwise.

Since the choice of single-qudit rotations \( U_\tau \) does not affect the purities [see Eq. (S.66)], we can additionally average the purities over \( U_\tau \) without loss of generality. It is also convenient to split the Liouvillian operator into two parts as

\[
\frac{d}{dt} P_G = \sum_{j:O_j \in G} \kappa_j M_1(\rho, O_j, G) + \sum_{j:O_j \notin G} \kappa_j M_2(\rho, O_j, G),
\]

where \( M_1 \) and \( M_2 \) correspond, respectively, to measurements inside and outside the set \( G \):

\[
M_1(\rho, O_j, G) = 8 \left( \langle \text{Tr}_G(\rho_G O_j) \rangle^2 - 2 \text{Tr} \rho_G O_j \text{Tr}_G (\rho_G^2 \text{Tr}_G \rho_G O_j) \right)_{\text{circ}, U_\tau},
\]

\[
M_2(\rho, O_j, G) = 8 \left( \langle \text{Tr}_G (\text{Tr}_F(G) \rho_O(t)) \rangle^2 - 2 \text{Tr} \rho_O(t) \text{Tr}_G (\text{Tr}_F(G) \rho_O(t) \rho_G) + (\text{Tr} \rho_O(t) \text{Tr}_G \rho_G \rho_G) \right)_{\text{circ}, U_\tau}.
\]

In the limit of vanishing correlation time, \( \kappa_\tau \rightarrow 0 \), the unitaries \( U_{\tau,i}(t) \) at each time \( t \) can be considered as independent Haar-random matrices. Therefore, the average of the density operator \( \rho \) over \( U_{\tau,i} \) and the average of observable \( O_j(t) \) at time \( t \) over \( U_{\tau,i}(t) \) can be performed independently of each other.

Then, after averaging \( O_j(t) \) over \( U_{\tau,i}(t) \), we obtain

\[
M_1(\rho, O_j, G) = \frac{8 \text{Tr}_\Omega \rho_G^2}{q^2 - 1} \left( \langle \text{Tr}_G \rho_G^2 \text{Tr}_\Omega \rho_O^2 - 2 \text{Tr} \rho_G \text{Tr}_\Omega \rho_O^2 \rangle \right)_{\text{circ}, U_\tau},
\]

\[
M_2(\rho, O_j, G) = \frac{8 \text{Tr}_\Omega \rho_G^2}{q^2 - 1} \left( \langle \text{Tr}_G \rho_O^2 \text{Tr}_\Omega \rho_G^2 + 2 \text{Tr} \rho_O \text{Tr}_\Omega \rho_G \rangle \right)_{\text{circ}, U_\tau}.
\]

We notice that \( M_2 \) can be written in a compact way,

\[
M_2(\rho, O_j, G) = \frac{8 \text{Tr}_\Omega \rho_G^2}{q^2 - 1} \left( \| \rho_{G \cup O_j} - \rho \otimes \rho_O \|^2 \right)_{\text{circ}, U_\tau}.
\]

where \( \| \cdot \|_2 \) is a 2-norm.

Given that the overall state of the system is pure, we can also simplify \( M_1 \) in Eq. (S.86) using the property

\[
\frac{d}{dt} P_G = \frac{d}{dt} P_{F \setminus G}.
\]

Since variables \( \kappa_j \) are independent variables that can take arbitrary values, Eq. (S.83) will satisfy Eq. (S.89) only if

\[
M_1(\rho, O_j, G) = M_2(\rho, O_j, F \setminus G).
\]

Combining Eqs. (S.88) and (S.90), we obtain

\[
M_1(\rho, O_j, G) = \frac{8 \text{Tr}_\Omega \rho_G^2}{q^2 - 1} \left( \| \rho_{(F \setminus G) \cup O_j} - \rho_{(F \setminus G) \otimes \rho_O} \|^2 \right)_{\text{circ}, U_\tau}.
\]

Therefore, the following expression holds for the combined evolution under Hamiltonian and measurement dynamics:

\[
\frac{d}{dt} P_G = -i \sum_i \alpha_i \left( P_G + \frac{P_{G \cup \omega_i}}{d_\omega} - \frac{P_{G \setminus \omega_i}}{d_\omega} \right)_{\div(G \setminus G)} + \sum_{j:O_j \in G} \zeta_j \left( \| \rho_{O_j \cup (F \setminus G)} - \rho \otimes \rho_{F \setminus G} \|^2 \right)_{\text{circ}} + \sum_{j:O_j \notin G} \zeta_j \left( \| \rho_{O_j} - \rho \otimes \rho_O \|^2 \right)_{\text{circ}},
\]

where \( \zeta_j = 8 \text{Tr}_\Omega \rho_G^2 \kappa_j / (q^2 - 1) \), and we removed the average over \( U_\tau \) in the expressions in the second line since these expressions, like purity, are invariant under the \( U_\tau \) rotation defined in Eq. (S.65). The second line of this equation yields Eq. (15) in the main text.

In the mean-field approximation, the correlation distance can be approximated as

\[
\left\| \rho_{G \cup O_j} - \rho \otimes \rho_O \right\|_2 \approx P_{G \cup O_j} - P_G P_O.
\]
The accuracy of this approximation is illustrated in Fig. S2(c) for a 9-qubit system in a random matrix-product state, similar to Eq. (S.9). As in the case of the annealed approximation, the error of the mean-field approximation strongly depends on the bond dimension $N_b$ and rapidly decreases from $\epsilon \sim 1$ for $\log_2 N_b = 1$ down to $\epsilon \sim 10^{-2}$ for $\log_2 N_b = 5$.

**Relation to the discrete case.** Let us first derive Eq. (2) in the main text from Eq. (14). Consider a situation where a single stochastic Hamiltonian term $h$ with strength $\alpha$ and support $\omega$ is applied to the system. The purities $P_G(\omega)$ and $P_{G,\Delta \omega}$ remain unchanged throughout the evolution. Therefore, the evolution of purity $P_G$ can be evaluated by solving the following closed set of equations:

$$\frac{d}{dt} P_G = -\alpha \left( P_G + \frac{P_G \Delta \omega}{d_\omega} - \frac{P_G \cap \omega}{d_G \cap \omega} - \frac{P_G \cup \omega}{d_G \cup \omega} \right),$$

(S.94)

$$\frac{d}{dt} P_{G,\Delta \omega} = -\alpha \left( P_{G,\Delta \omega} + \frac{P_G \cap \omega}{d_\omega} - \frac{P_G \cup \omega}{d_G \cup \omega} \right).$$

(S.95)

One then immediately finds that the steady-state solutions $P_G' = \lim_{t \to \infty} P_G(t)$ and $P_{G,\Delta \omega}' = \lim_{t \to \infty} P_{G,\Delta \omega}(t)$ of these equations yield Eq. (2) in the main text.

Let us now derive Eq. (3) in the main text from Eq. (15). Consider the mean-field approximation for the continuous-measurement evolution in Eq. (15) restricted to the case where the measurement is performed on a single qudit $\Omega$:

$$\frac{dP_G}{dt} = \zeta \left( P_{G,\Omega} - P_G P_\Omega \right) \delta_{\Omega \in F \setminus G} + \zeta \left( P_{(F \setminus G),\Omega} - P_{F \setminus G} P_\Omega \right) \delta_{\Omega \in G}.$$ 

(S.96)

Let us further consider the case $\Omega \notin G$, i.e., the qudit being measured is outside of the subsystem of interest. The dynamics can then be evaluated by solving the following closed set of equations:

$$\frac{d}{dt} P_G = \zeta \left( P_G - P_\Omega \right),$$

(S.97)

$$\frac{d}{dt} P_{G,\Omega} = \zeta \left( P_G - P_\Omega \right),$$

(S.98)

$$\frac{d}{dt} P_\Omega = \zeta \left( 1 - P_\Omega^2 \right).$$

(S.99)

Here we used identities $P_{F \setminus \Omega} = P_\Omega$, $P_{(F \setminus (G \cup \Omega)) \setminus \Omega} = P_G$, and $P_{(F \setminus (G \cup \Omega)) \setminus \Omega} = P_G$.

As expected, the case where qubit $\Omega$ is disentangled (i.e., $P_\Omega = 1$) is a fixed point of Eq. (S.99). For general $P_\Omega(0)$ and assuming time-independent $\zeta$, the solution of Eq. (S.99) is

$$P_\Omega(t) = 1 - \frac{2}{\mu \exp(2\zeta t) + 1}, \quad \mu = \frac{1 + P_\Omega(0)}{1 - P_\Omega(0)}.$$ 

(S.100)

By introducing new variables $S^+ = P_G + P_{G,\Omega}$ and $S^- = P_G - P_{G,\Omega}$, we can decouple the remaining two equations:

$$\frac{dS^+}{dt} = \zeta (1 - P_\Omega) S^+,$$

(S.101)

$$\frac{dS^-}{dt} = -\zeta (1 + P_\Omega) S^-.$$ 

(S.102)

Solving these equations and using Eq. (S.100), we find

$$S^+(t) = S^+(0) \frac{\mu + 1}{\mu + \exp(-2\zeta t)}$$

(S.103)

$$S^-(t) = S^-(0) \frac{\mu + 1}{\mu + \exp(-2\zeta t)} \exp(-2\zeta t).$$

(S.104)

In the limit $\zeta t \to \infty$, weak continuous measurement must reproduce a projective measurement. Indeed,

$$\lim_{t \to \infty} S^+(t) = \frac{2S^+(0)}{1 + P_\Omega(0)}, \quad \lim_{t \to \infty} S^-(t) = 0,$$

(S.105)

which implies

$$\lim_{t \to \infty} P_G(t) = \frac{P_G(0) + P_{G,\Omega}(0)}{1 + P_\Omega(0)}.$$ 

(S.106)

which, in turn, yields Eq. (3) in the main text. The solution for the case $\Omega \in G$ can be obtained in a similar way leading to the same result. We thus find that, in the mean-field approximation, the long-time limit of the evolution for the purity under a weak continuous measurement leads to the corresponding result for the projective measurement under the annealed approximation.
