ABSTRACT

**Aims.** We investigate the energy sources of the infrared (IR) emission and their relation to the radio continuum emission at various spatial scales within the Scd galaxy M33.

**Methods.** We use the data at the *Spitzer* wavelengths of 24, 70, and 160 µm, as well as recent radio continuum maps at 3.6 cm and 20 cm observed with the 100–m Effelsberg telescope and VLA, respectively. We use the wavelet transform of these maps to a) separate the diffuse emission components from compact sources, b) compare the emission at different wavelengths, and c) study the radio–IR correlation at various spatial scales. An Hα map serves as a tracer of the star forming regions and as an indicator of the thermal radio emission.

**Results.** The bright HII regions affect the wavelet spectra causing dominant small scales or decreasing trends towards the larger scales. The dominant scale of the 70 µm emission is larger than that of the 24 µm emission, while the 160 µm emission shows a smooth wavelet spectrum. The radio and Hα maps are well correlated with all 3 MIPS maps, although their correlations with the 160 µm map are weaker. After subtracting the bright HII regions, the 24 and 70 µm maps show weaker correlations with the 20 cm map than with the 3.6 cm map at most scales. We also find a strong correlation between the 3.6 cm and Hα emission at all scales.

**Conclusions.** Comparing the results with and without the bright HII regions, we conclude that the IR emission is influenced by young, massive stars increasingly with decreasing wavelength from 160 to 24 µm. The radio–IR correlations indicate that the warm dust–thermal radio correlation is stronger than the cold dust–nonthermal radio correlation at scales smaller than 4 kpc. A perfect 3.6 cm–Hα correlation implies that extinction has no significant effect on Hα emitting structures.

1. Introduction

One of the most important discoveries of the IRAS mission was the correlation between the IR and radio continuum luminosities for a sample of galaxies (e.g., Helou et al. 1985; de Jong et al. 1985; Gavazzi et al. 1986). Beck & Golla (1988) showed that this correlation also holds within several spiral galaxies including M31 and M33. The radio–IR correlation was explained by Helou et al. (1985) and de Jong et al. (1985) as a direct and linear relationship between star formation and IR emission. On the other hand, there was concern that the cold dust emission, as a component of the far–infrared (FIR) emission, might not be directly linked to the young stellar population. For the nearby galaxy M31, Hoernes et al. (1998), using IRAS data, found a good correlation between the emission of thermal–radio/warm dust and nonthermal–radio/cold dust with slightly different slopes. They explained the latter correlation by a coupling of the magnetic field to the gas mixed with the cold dust. Such a coupling was also considered by Niklas & Beck (1997) as the origin of the global radio–FIR correlation. Hinz et al. (2004) found similar behavior in M33.
Table 1. Images of M33 used in this study

| Wavelength | Resolution | Telescope |
|------------|------------|-----------|
| 20 cm      | 51"        | VLA 1     |
| 20 cm      | 540"       | Effelsberg 2 |
| 3.6 cm     | 84"        | Effelsberg* |
| 160 μm     | 40"        | Spitzer3  |
| 70 μm      | 18"        | Spitzer3  |
| 24 μm      | 6"         | Spitzer3  |
| 6570 Å (Hα) | 2" (pixel size) | KPNO4     |

The possibility that the relationship between the radio and IR emission might vary within galaxies (e.g., Gordon et al. 2004) due to the range of individual conditions makes it necessary to repeat these kinds of studies with improved data in the most nearby galaxies. Furthermore, it is uncertain what component of a galaxy provides the energy that is absorbed and re-radiated in the IR (Kennicutt 1998). For example, from the close correspondence between hydrogen recombination line emission and IR morphologies, Devereux et al. (1994); Devereux et al. (1996, 1997) and Jones et al. (2002) argued that the FIR is powered predominantly by young O/B stars.

Another problem that hinders a better understanding of the radio–IR correlation is the separation of thermal and nonthermal components of the radio continuum emission using a constant nonthermal spectral index (the standard method). Although this assumption leads to a proper estimation for global studies, it cannot produce a realistic image of the nonthermal distribution in highly resolved and local studies within a galaxy, because it is unlikely that the nonthermal spectral index remains constant across a galaxy (Fletcher et al. 2004).

M33 (NGC 598) is the nearest late–type spiral galaxy, at a distance of 840 kpc (Freedman et al. 1991) and is ideal to compare the morphologies of different components of such a galaxy. With an inclination of $i = 56^\circ$ (Regan & Vogel 1994), it is seen nearly face on. The central position of M33 given by de Vaucouleurs & Leach (1981) is RA(2000) = $1^h 33^m 51.0^s$ and DEC(2000) = $30^\circ 39' 37.0''$. The position angle of the major axis is PA $\sim 23^\circ$ (Deul & van der Hulst 1987).

With the Multiband Imaging Photometer Spitzer (MIPS, Rieke et al. 2004) data at 24, 70, and 160 μm, it is possible to interpret the morphology of M33. Hinz et al. (2004) compared the first epoch data of MIPS with Hα images and radio continuum data at 6 cm, using a Fourier filtering technique to distinguish different emission components. We now have multiple epochs of MIPS data that provide a significantly higher–quality image of M33, for example in the suppressing of stripes along the direction of scan caused by slow response from the far infrared arrays. In addition, we use a wavelet analysis technique that Frick et al. (2001) have shown to be more robust against noise than Fourier filtering. Furthermore, the wavelet technique provides more precise and easier analysis of the scale distribution of emission energy, especially at smaller scales of the emitting structures. We apply a 2D–wavelet transformation to separate the diffuse emission components from compact sources in MIPS mid– and far–infrared (hereafter IR), radio (at 3.6 and 20 cm), and Hα images (Table 1).

The classical correlation between IR and radio emission has been at the whole galaxy level. However, such a correlation can be misleading when a bright, extended central region or an extended disk exists in the galactic image. This technique gives little information in the case of an anticorrelation on a specific scale (Frick et al. 2001). The ‘wavelet cross–correlation’ introduced by Frick et al. (2001) calculates the correlation coefficient as a function of the scale of the emitting regions. Hughes et al. (2006) applied this method to study the radio–FIR correlation in the Large Magellanic Cloud (LMC).

Hippelein et al. (2003) found evidence for a local radio–FIR correlation in the star forming regions of M33. In this paper, we investigate this correlation not only for the star forming regions but also for other structures within M33 at spatial scales between 0.4 and 4 kpc using the wavelet cross–correlation. Instead of the standard method to separate the thermal and nonthermal components of the radio continuum emission, we use the radio continuum data both at high and low frequency (3.6 and 20 cm, respectively). We compare our radio images to the Hα image (which is taken as a tracer of the thermal free–free emission) to distin-
Fig. 1. The 3.6 cm radio map of M33 (left panel) observed with the 100–m radio telescope in Effelsberg, and the combined 20 cm radio map (right panel) from the VLA and Effelsberg observations. The half power beam widths (HPBWs) of 84″ and 51″, respectively, are shown in the lower left corners.

guish the components of the radio continuum emission.

We study the structural characteristics of the MIPS IR images using the 2D-wavelet transformation in Sect. 3. The distribution of the emission energy at both IR and radio regimes and the dominant spatial scale at each wavelength are discussed in Sect. 4. We show how the different MIPS images are correlated at different scales and how the radio–IR correlation varies with components of the galaxy (e.g. gas clouds, spiral arms, extended central region and extended diffuse emission) in Sect. 5. In Sec. 6, we use the Hα map to probe the energy sources of IR and radio emission. Results and discussion are presented in Sect. 7. An overview of the preliminary results was presented in Tabatabaei et al. (2005).

2. Observations and data reduction

Table 1 summarizes the data used in this work. The 3.6 cm radio observations were made with the 100-m Effelsberg telescope during several periods (18 nights) between August 2005 and March 2006. The reduction was done in the NOD2 data reduction system (Haslam 1974). The r.m.s. noise after combination (Emerson & Graeve 1988) of 36 coverages is ∼220 µJy/beam. We also observed M33 at 20 cm with the B-band VLA D-array during 5 nights in November 2005 and January 2006 (from 06 to 08-11-05, 13-11-05, and 06-01-06). The reduction, calibration, and mozaicing of 12 fields were accomplished using the standard AIPS programs. The VLA interferometric data will miss much of the extended emission of the galaxy. For example, Viallefond et al. (1986a) showed that the WSRT interferometric map at 1.4 GHz accounted for only about 16% of the total emission. Therefore, we combined the VLA map with the new Effelsberg 20 cm map (Fletcher 2001) to recover the emission from extended structures in M33. The r.m.s. noise of the final map is ∼180 µJy/beam. Detailed descriptions of the observations and data reduction of the radio data will be given in Tabatabaei et al. (in prep.). Both radio maps are shown in Fig. 1.

1 The 100–m telescope at Effelsberg is operated by the Max-Planck-Institut für Radioastronomie (MPIfR) on behalf on the Max–Planck–Gesellschaft.

2 The VLA is a facility of the National Radio Astronomy Observatory. The NRAO is operated by Associated Universities, Inc., under contract with the National Science Foundation.
M33 was mapped in the IR by MIPS (Rieke et al. 2004) four times on 29/30 December 2003, 3 February 2005, 5 September 2005, and 9/10 January 2006. Each observation consisted of medium-rate scan maps with 1/2 array cross-scan offsets and covering the full extent of M33. The basic data reduction was performed using the MIPS instrument team Data Analysis Tool versions 3.02-3.04 (Gordon et al. 2005). At 24 µm extra steps were carried out to improve the images includ-
Fig. 3. MIPS maps of M33 at 40″ resolution (first column) and their wavelet decompositions for 4 different scales: 80″ (second column), 383″ (third column), 626″ (forth column), and 1024″ (fifth column). At the distance of 840 kpc, 1″ is equivalent to 4 pc. The maps at 24, 70, and 160μm are shown from top to bottom. Before the decomposition, huge HII regions like NGC 604 were subtracted from the original images (Sect. 4). Maps are shown in RA–DEC coordinate system and centered at the center of the galaxy. The field size is 34′ × 41′.

The 24 μm image used consisted of just the 9/10 January 2006 observations as the depth reached in a single mapping was sufficient for this work. The 70 μm image used was a combination of the last three observations as the 29/30 December 2003 70 μm map suffered from significant instrumental residuals. These instrumental residuals were much reduced when the operating parameters of the 70 μm array were changed after the first M33 map was made and before the second. The 160 μm image used consisted of a combination of all four maps. The combination of multiple maps of M33 taken with different scan mirror angles results in a significant suppression of residual instrumental signatures (seen mainly as low level streaking along the scan mirror direction). The images used in this work have exposure times of ∼100, 120, and 36 seconds/pixel for 24, 70, and 160 μm, respectively.

The Hα observations by Hoopes & Walterbos (2000) were carried out on the 0.6 meter Burrell–Schmidt telescope at the Kitt Peak National Observatory, providing a 68′ × 68′ field of view. The MIPS and Hα images are shown in Fig. 2.

To obtain a proper comparison with the 3.6 cm radio map, all images of M33 were convolved to the angular resolution of 84″. For higher angular resolution studies, maps at 18″, 40″, and 51″ were also made. The PSF (point spread function) of the MIPS data is not Gaussian, in contrast to that of...
the radio data. Thus, convolutions of the MIPS images were made using custom kernels created using Fast Fourier Transforms (FFTs) to account for the detailed structure of the MIPS PSFs. Details of the kernel creation can be found in Gordon et al. (2007, in prep.). After convolution, the maps were normalized in grid size, rotation and reference coordinates. Then, they were cut to a common field of view (3′′ × 4′′ in RA and DEC, respectively).

In the following sections, we discuss the results with and without bright compact sources at each resolution to investigate how these sources affect the energy distribution at each wavelength and the correlations between wavelengths. After convolving to each resolution, the bright sources, common to all images, were subtracted using Gaussian fits including baselevels (‘Ozmapax’ program in the NOD2 data reduction system). For instance, the giant H II complexes NGC604 and NGC595 were subtracted at all resolutions. We also subtracted strong steep-spectrum background radio sources from the 20 cm image. Detailed descriptions of the source subtraction at each resolution are given in Sect. 4.

3. Wavelet analysis of IR emission

Wavelet analysis is based on a spatial–scale decomposition using the convolution of the data with a family of self–similar basic functions that depend on the scale and location of the structure. Like the Fourier transformation, the wavelet transformation includes oscillatory functions; however, in the latter case these functions rapidly decay towards infinity. As a result, Frick et al. (2001) show that the wavelet method is more resistant to noise and the smoother spectra allow better determination of the true frequency structure. The cross–correlation of wavelet spectra lets us compare the structures at different wavelengths. After convolving the original maps and the decomposed maps at 4 scales, the arm–structure anymore. This structure can be identified as an underlying diffuse disk with a general radial decrease in intensity. The similarity in M33, we use the ‘Pet–Hat’ wavelet that was introduced by Frick et al. (2001) and applied there to NGC6946. It is defined in Fourier space by the formula:

$$\psi(k) = \left\{ \begin{array}{ll} \cos^2\left(\frac{\pi}{2}\log\frac{k}{2\pi}\right) & \pi \leq k \leq 4\pi \\ 0 & \pi > k \text{ or } k > 4\pi, \end{array} \right. \quad (2)$$

where \(k\) is the wavevector and \(k = |k|\).

We decomposed the Spitzer images into 10 different scales \(a\) to compare the morphologies at 24, 70, and 160 \(\mu m\) at each scale. Fig. 3 shows the original maps and the decomposed maps at 4 scales. The original 24 and 70 \(\mu m\) maps were smoothed to the MIPS 160 \(\mu m\) PSF with FWHM (full width half maximum) = 40′′ before decomposition. The maps at scale \(a = 80′′\) (0.3 kpc) show the smallest detectable emitting structures. Most of the morphological differences among the MIPS images are found at this scale. At scale \(a = 383′′\) (1.5 kpc), the prominent structures are spiral arms and the center of the galaxy. The central extended region is more pronounced at scale \(a = 628′′\) (2.5 kpc). The emission emerges from a diffuse structure at scale \(a = 1024′′\) (4 kpc), and it is not possible to distinguish the arm–structure anymore. This structure can be identified as an underlying diffuse disk with a general radial decrease in intensity. The similarity of the 4 kpc maps at different wave lengths indicates

---

3 To have both physically meaningful results and a sufficiently large number of independent points, the scale \(a\) varies between a minimum of about twice the resolution and a maximum of about half of the image size, \(a < 1100′′\), for all images studied in this paper.
that the large scale diffuse emission has the same structure at different mid- and far-infrared wavelengths.

At the smallest scale, the emission emerges from spot-like features aligned along filaments with the width of the scale. At 24 μm smoothing, diffuse filaments are more pronounced at 160 μm. As shown in the next section, the fraction of the energy at this scale at 160 μm is less than that at 24 μm. The situation in the 70 μm map is in between the 24 and 160 μm maps. It seems that the star forming regions provide most of the energy of the 24 and 70 μm emission, if the spots correspond to these regions, as is discussed in the following sections.

4. Spectral characteristics of IR and radio maps

In this section, we demonstrate how the wavelet spectra can be used to investigate the scaling properties of the emission. This spectrum is defined as the energy in the wavelet coefficients of scale a [Frick et al. 2001]:

\[ M(a) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} |W(a,x)|^2 dx. \]  

(3)

After smoothing the 24 μm map to the MIPS 70 μm PSF with FWHM = 18″, about 40 bright sources (mostly corresponding to HII regions) were subtracted from both maps (equivalent to removing sources with fluxes higher than the lower limits, \( S(\lambda), \) given in Table 2.). Fig. 4 shows the wavelet spectra, \( M(a) \), of the 24 μm and 70 μm maps before and after source subtraction. Clearly, the small scales are the dominant scales before source subtraction. The scale at which the wavelet energy is maximum is \( \sim 70″ \) (280 pc) at 24 μm and \( \sim 110″ \) (440 pc) at 70 μm. After source subtraction, the spectra become flatter. The larger size of the dominant scale at 70 μm caused by these sources (by a factor of \( \sim 1.6 \) at this resolution) indicates a slightly more extended distribution of dust grains emitting at 70 μm than 24 μm in the vicinity of star forming regions. Moreover, the ratio of the maximum to minimum energy in the original spectrum at 24 μm is larger (by a factor of 3) than that at 70 μm. This indicates that either star forming regions provide more energy for the 24 μm emission, or the large-scale diffuse emission is stronger at 70 μm than 24 μm.

At the next angular resolution, 51″, the HPBW (half power beam width) of the 20 cm radio map, 15 bright sources (HII regions) visible at all maps were subtracted from the 20 cm map and the smoothed 24, 70, and 160 μm IR maps. In addition to these sources, 9 background radio sources plus the supernova remnants SN1, SN2, and SN3 [Viallefond et al. 1986b] were subtracted from the 20 cm radio map. The wavelet spectra of the MIPS and 20 cm radio maps at this resolution are plotted in Fig. 5. The \( \text{H} \alpha \) spectrum is also given for comparison. The 24 and 70 μm maps show a smoothed version of their distributions in Fig. 4 (the linear smoothing factor is \( \sim 3 \) between Figs. 4 and 5). However, the effect of the sources can still be seen by comparing the left panel with the source subtracted spectra in the right panel.

The 160 μm map is hardly influenced by the smoothing, as its original resolution is 40″ (the smoothing factor is \( \sim 1.3 \)). The 160 μm spectrum is more similar to the 70 μm spectrum than to the other spectra. It seems that the compact sources have less effect on the energy distribution at 160 μm, because the smallest scale is not the dominant scale. Hence, there is no important change in the spectrum after the source subtraction. The energy shows an increase at the scale of complexes of dust and gas clouds (\( \sim 250″ \) or 1 kpc), then a second increase in transition to the large-scale structures or diffuse dust emission.

The spectrum of the 20 cm radio image is also dominated by bright sources. There is a maximum at the scale \( a = 140″ \), then a decrease towards the larger scales with a slope of -0.9. However, a flat spectrum remains for the scales less than the size of the central extended region (\( \sim 600″ \)) after the source subtraction.

---

**Table 2.** Source subtraction thresholds \( S(\lambda) \) and number of subtracted sources at different spatial resolutions.

| Resolution | Subtracted sources | \( S(24 \mu m) \) | \( S(70 \mu m) \) | \( S(160 \mu m) \) | \( S(20 \text{cm}) \) | \( S(3.6 \text{cm}) \) |
|------------|-------------------|----------------|----------------|----------------|----------------|----------------|
| arcsec     | #                 | \( \mu \text{Jy/arcsec}^2 \) | \( \mu \text{Jy/arcsec}^2 \) | \( \mu \text{Jy/arcsec}^2 \) | \( \mu \text{Jy/beam} \) | \( \mu \text{Jy/beam} \) |
| 18         | 40                | 460            | 2650           | –              | –              | –              |
| 51         | 15                | 115            | 1570           | 2865           | 7190           | –              |
| 84         | 11                | 85             | 900            | 2340           | 8260           | 5780           |
Fig. 5. The wavelet spectra of the 20 cm radio and IR images at 51\arcsec resolution before (left) and after (right) subtraction of the same sources. For comparison, the wavelet spectrum of the H\alpha emission is also plotted. The data points correspond to the scales 112, 143, 183, 234, 299, 383, 490, 626, 800, 1024\arcsec. The spectra are shown in arbitrary units.

Fig. 6. The wavelet spectra of the 3.6 cm radio and IR images at 84\arcsec resolution before (left) and after (right) subtraction of the same sources. For comparison, the spectrum of the H\alpha emission is also plotted. The data points correspond to the scales 210, 250, 298, 356, 424, 505, 602, 718, 856, 1020\arcsec. The spectra are shown in arbitrary units.

The spectra of all the maps at the resolution of the 3.6 cm data (HPBW = 84\arcsec) are shown in Fig. 6 (left panel). The spectra after subtracting the 11 brightest HII regions are plotted in the right panel. Again, because of these sources, the small scales are dominant at 3.6 cm. As shown in comparing the left and right panels, they also are seen in all the infrared bands, strongly at 24\,\mu m and much more weakly at 160\,\mu m. Here, the smoothing effect is seen in all 3 MIPS wavelet spectra.

Before source subtraction, the 20 and 3.6 cm spectra are similar to each other and to the H\alpha spectrum up to the scale of the central extended region, \(~600\arcsec (2.5 \text{kpc})\). All three spectra become steeper between \(a \sim 600\arcsec\) and \(a \sim 850\arcsec\), which means that the wavelet energy from structures with scales of about half of the size of the galaxy (\(~900\arcsec\) or 3.7 kpc) is not as significant as that from smaller structures. It seems that a minimum in the wavelet spectra of the radio and H\alpha emission, as was also shown in NGC 6946 (see Fig. 7 in Frick et al. 2001), is a characteristic of this scale. However, while this decrease disappears in the 3.6 cm and H\alpha spectra after source subtraction, it remains in the 20 cm spectrum. This implies that besides the bright HII regions there are sources of nonthermal emission within the spiral arms and central extended region which emit significantly
To estimate how much of the wavelet energy \( M(a) \) is provided by the subtracted sources, we consider the following definition:

\[
\Delta(a) \equiv M_{or.}(a) - M_{s.s.}(a) / M_{or.}(a),
\]

where \( M_{or.}(a) \) and \( M_{s.s.}(a) \) represent the wavelet energy before and after source subtraction. Table 3 shows the fraction of energy produced by the 11 HII regions in IR and at 3.6 cm for 3 different scales (at 84\arcsec resolution). The corresponding fractions at 20 cm are not shown in this table, as some nonthermal radio sources were also subtracted at this wavelength. The emission at 24 \( \mu \)m has the largest energy fraction \( \Delta(a) \) at all scales. The smallest \( \Delta(a) \) occurs at 160 \( \mu \)m. This indicates that HII regions play a more important role in providing energy for dust emission at 24 \( \mu \)m than at 160 \( \mu \)m.

We estimate the uncertainties of the wavelet energies of each map by making a noise map with the distribution and amplitude of the real noise in the corresponding observed map. A linear combination of uniform and Gaussian distributions simulates the real noise in each observed image. The wavelet spectra of the derived noise maps were obtained using Eq. 3. The resulting wavelet energies of the noise maps are taken as the uncertainties of the wavelet energies of the observed maps at different scales. The estimated values are at least three orders of magnitude less than the wavelet energies of the observed maps. Therefore, the results from our wavelet spectrum analysis are not substantially affected by the noise in the maps.

5. Wavelet cross-correlations

A useful method to compare images at different wavelengths is the wavelet cross-correlation. The wavelet cross-correlation coefficient at scale \( a \) is defined as:

\[
r_w(a) = \frac{\int \int W_1(a, x) W_2^*(a, x) d\mathbf{x}}{[M_1(a)M_2(a)]^{1/2}},
\]

where the subscripts refer to two images of the same size and linear resolution. The value of \( r_w \) varies between -1 (total anticorrelation) and +1 (total correlation). Plotting \( r_w \) against scale shows how well structures at different scales are correlated in intensity and location. The error is estimated by the degree of correlation and the number of independent points, \( n \):

\[
\Delta r_w(a) = \frac{\sqrt{1 - r_w^2}}{\sqrt{n - 2}},
\]

where, \( n = 2.13 \left(\frac{L}{a}\right)^2 \), and \( L \) is the size of the maps.\
First, we examine the cross-correlations between the 3 MIPS maps of M33 (Fig. 7). There are significant correlations between each pair of the MIPS maps at different scales within $0.4 < a < 4$ kpc, as $r_w > 0.75$ [Frick et al. 2001]. These scales include gas clouds, spiral arms, and the central extended region. Comparing the plots, the 24–160 µm correlation is weaker than the two other correlations, especially at scales smaller than the spiral arms ($a < 400''$). This is due to significantly different contributions of HII regions in providing energy for dust emission at 24 and 160 µm (see Table 3), as the 24–160 µm correlation coefficients increase after subtracting these sources. This indicates that HII regions influence the correlations at scales larger than their sizes (the width of the huge HII region NGC604 is about 100'' or 0.4 kpc).

Second, we study the cross-correlations between the infrared and the radio continuum emission at 3.6 cm. As shown in Fig. 8, the correlations between 3.6 cm radio and the three infrared emission are strong at all scales. At scales smaller than the width of the spiral arms (1.6 kpc), the correlations are higher between 3.6 cm and 24 µm emission (and also 70 µm) than between 3.6 cm and 160 µm emission. The source subtraction reduces the 3.6 cm–24 µm and 3.6 cm–70 µm correlations at scales smaller than the spiral arms. This indicates that young massive stars are the most common and important energy sources of the 3.6 cm, 24 and 70 µm emission at these scales.

Third, the cross-correlations with the radio continuum emission at 20 cm are presented in Fig. 9. Before the source subtraction, the correlations between 20 cm radio and the three IR bands are strong at scales smaller than the width of the spiral arms. After the source subtraction, the coefficients of the IR–20 cm correlations decrease dramatically so that they become less than 0.75 at small scales. The reason is possibly that besides HII regions there are other unresolved sources of the 20 cm radio emission like supernova remnants that are stronger than at 3.6 cm but do not emit significantly in the infrared. Studies within our Galaxy have demonstrated that the ratio of far-infrared to radio continuum emission for supernova remnants is much smaller than that for HII regions [Fuerst et al. 1987].

Comparing Fig. 8 with Fig. 9, a drop in correlation coefficient at the scale of 800'' (3.2 kpc) is more prominent in the MIPS correlations with 20 cm than with 3.6 cm. This is due to the strong minimum in the 20 cm spectrum at this scale (Fig. 5) that persists even after the source subtraction (in contrast to the situation in the 3.6 cm spectrum shown in Fig. 6).

6. Comparison with Hα

If we take the Hα emission as a tracer of star forming regions that both heat the warm dust and ionize the gas giving the free–free emission, we expect a correlation between Hα emission, IR and thermal radio emission. The cross–correlations involving Hα and IR images are shown in Fig. 10. The significant correlation of Hα with the 24 and 70 µm images at the smallest scale confirms that most of the compact structures in the MIPS decomposed maps at 24 and 70 µm (Fig. 3) correspond to the HII regions. The 160 µm emission is also correlated with Hα.
Fig. 9. The correlation of the 20 cm radio and IR before and after subtraction of the same sources at 51″ resolution (please note that this Fig. starts from 100″ and not 200″).

emission, although the correlations are weaker than the correlations at 24 and 70 μm. It is deduced that the role of star forming regions in heating the dust, even the cold dust (emitting mainly at 160 μm), is generally important at scales smaller than 4 kpc.

Between Hα and 3.6 cm there is a perfect correlation for both small–scale and extended structures: \( r_w \geq 0.95 \) (bottom panel in Fig. 10). This is not surprising as the wavelet spectra of the Hα and 3.6 cm maps are very similar (see Fig. 6). Thus, not only are the star forming regions mostly responsible for the 3.6 cm emission, but also the radio continuum emission is dominated by the thermal free–free emission at 3.6 cm for \( a < 4 \) kpc.

After smoothing the 20 cm map to the spatial resolution of the 3.6 cm map, we obtain the Hα–20 cm correlation (Fig. 10). At scales smaller than 600″ or 2.4 kpc, the coefficients are the same as for the Hα–3.6 cm correlation. This means that the bright HII regions are also important sources of the 20 cm radio emission. It seems that the correlation decreases at larger scales, but it is not certain because of the large errors.

7. Discussion

We studied the spectral characteristics of the MIPS mid– and far–infrared, radio and Hα maps and obtained cross–correlation coefficients between pairs of maps. Here, we discuss the implications of our results for the understanding of the energy sources powering the IR and radio emission from M33. Further, we compare the results of our analysis on M33 with that of [Frick et al. (2001)](frick2001) on NGC 6946.
7.1. IR emission

From the wavelet analysis of the MIPS IR maps the following results are found.

- The 24 and 70 µm emission emerge mostly from the bright sources corresponding to star forming and HII regions. The influence of HII regions on the IR emission is highest at 24 µm (see Table 3). As expected, at small scales the 24 µm map is better correlated with the 70 µm than with the 160 µm map.
- The 160 µm emission emerges from both compact and extended structures. The compact structures correspond to star forming and HII regions. As shown in Table 3, the fraction of wavelet energy provided by the 11 brightest HII regions at 160 µm varies between 1/2 and 1/3 of that at 24 µm at different scales. The 160 µm map does not show small-scale dominance in its spectrum. The 160 µm spectrum shows an increase when it reaches the scale of complexes of dust and gas clouds of ~1 kpc, and a second increase in transition to the large-scale structures or diffuse dust emission.

While it is clear that the ionizing stars heat the warm dust, the mechanism heating the cold dust is still in debate. According to our wavelet analysis, the direct role of the young stellar population decreases with increasing IR wavelength. As shown in Table 3, at small scales (<200″ or 0.8 kpc), the relative contribution of the 11 brightest HII regions at 160 µm varies between 1/2 and 1/3 of that at 24 µm at different scales. The 160 µm map does not show small-scale dominance in its spectrum. The 160 µm spectrum shows an increase when it reaches the scale of complexes of dust and gas clouds of ~1 kpc, and a second increase in transition to the large-scale structures or diffuse dust emission.

7.2. Radio emission and radio–IR correlation

From the wavelet analysis of the radio maps we obtain the following results for the 3.6 and 20 cm emission from M33.

- The shape of the 3.6 cm wavelet spectrum is very similar to that of the Hα spectrum (Fig. 6) and, hence, there is a perfect correlation between 3.6 cm and Hα at all scales (Fig. 10). This indicates that not only the star forming regions are mostly responsible for the radio emission at 3.6 cm, but also the thermal (free-free) emission is the dominant component at this wavelength. But it could also be that the nonthermal (synchrotron) emission correlates well with the thermal emission. Our recent estimation of the thermal fraction of the 3.6 cm radio continuum emission gives $f_{th} \sim 50\%$ for the...
whole galaxy including the extended disk emission (Tabatabaei et al., in prep.). As a higher percentage of the thermal fraction is expected at scales $\leq 4$ kpc, this result is consistent with our wavelet study. The nearly parallel 3.6 cm and H$\alpha$ wavelet spectra indicates that extinction is scale–independent and has no significant effect on H$\alpha$ emitting structures.

- The combined 20 cm (VLA+Effelsberg) wavelet spectrum represents both compact and diffuse structures of thermal and nonthermal emission. The bright HII regions (or complexes) give strong contribution to the 20 cm emission. The strong H$\alpha$–20 cm correlation at scales smaller than the width of the central extended region ($\sim 2.5$ kpc) also indicates that the nonthermal emission correlates perfectly with the thermal emission at these scales.

- Generally, there are strong 3.6 cm–IR correlations at all scales in the range of 0.8–4 kpc within M33 (Fig. 8). The 3.6 cm correlations with 24 and 70 $\mu$m are better than that with 160 $\mu$m before subtracting bright HII regions. However, these correlations become approximately the same after subtracting HII regions. That is because the 24 and 70 $\mu$m emission are more influenced by the HII regions than the 160 $\mu$m emission.

- The strong 20 cm–IR correlations are mainly due to the bright HII regions, as the correlations fall after source subtraction (Fig. 9). Here, the weakest correlation is between the 20 cm and the 24 $\mu$m maps. This indicates that the nonthermal sources which are associated with star forming regions are not as effective as HII regions in heating the dust.

In their multi–resolution analysis of the radio–IR correlation in the LMC, [Hughes et al. (2006)] found strong correlations in the regions where the thermal fraction of the radio emission is high. This is in agreement with our results that the 24 and 70 $\mu$m–radio correlations are higher before subtracting HII regions. Even, the 160 $\mu$m–20 cm correlation follows this pattern before subtracting the thermal radio regions. For NGC6946, [Frick et al. (2001)] also found a better correlation between the thermal 3.6 cm radio and IR emission up to scales of the width of spiral arms, although the nonthermal emission dominates in this galaxy [Ehle & Beck (1993)].

7.3. Comparison with NGC 6946

It is instructive to compare the results of the wavelet analysis of M33 with those obtained by Frick et al. (2001) for NGC 6946, which is also a late–type Scd galaxy.

NGC 6946 was studied at a linear resolution of 0.4 kpc corresponding to our analysis at 84$''$ HPBW. Comparing Fig. 6 (in this paper) to Fig. 7 in the Frick et al. (2001) paper at scales between 0.8 and 4 kpc, the dominant scale of the H$\alpha$ wavelet spectrum is at the scale of the width of the spiral arms (1.5 kpc) in NGC 6946, while in M33 it is at the smallest scale ($\sim 200''$ or 0.8 kpc in Fig. 6). Even after subtracting the 11 brightest HII regions the scales corresponding to the spiral arms ($\sim 400''$) are not dominant in M33. This is because the spiral arms in M33 are not as pronounced as those in NGC 6946. Instead, the H$\alpha$ emission in M33 has a rather clumpy distribution.

The spectrum of dust emission from NGC 6946 at 12–18 $\mu$m shown in Fig. 7 in the Frick et al. (2001) paper is more similar to the spectrum of dust emission from M33 at 160 $\mu$m than to that at 24 $\mu$m. So, the excess of hot dust emission near the massive stars found in M33 is not visible in NGC 6946.

Frick et al. (2001) found signatures of three–dimensional Kolmogorov–type turbulence [Kolmogorov (1941)] for the ionized gas (H$\alpha$ and thermal radio continuum emission at 3.6 cm) at scales less than 0.6 kpc in NGC 6946. An increasing part of the spectrum (log$I$–log$a$) with a slope of 5/3 is typical for this type of turbulence [Spangler 1991]. They obtained this slope considering the first point at the scale of 0.3 kpc (the resolution of their maps was 0.4 kpc), making the slope estimate of 5/3 uncertain. At the same resolution we cannot investigate this turbulence for M33, as the smallest scale in Fig. 6 is larger than 0.6 kpc. However, at higher spatial resolutions the spectra of the radio, IR, and H$\alpha$ emissions from M33 do not show such an increase at scales less than 0.6 kpc (Figs. 4 and 5). The steepest increasing slope is about 1.1 at scales between 140 and 320 pc (in the 24 $\mu$m spectrum) (Fig. 4). The slopes become less at 51$''$ resolution (Fig. 5). They vary between 0 and 0.6 at increasing parts of the spectra and between 0 and -0.9 at decreasing parts of the spectra. After subtracting HII regions, the slopes become even flatter.

Comparing Fig. 12 in the Frick et al. (2001) paper to Fig. 10 (in this paper), the 3.6 cm–H$\alpha$ cross–correlation coefficients are less at the small scales in NGC 6946 than in M33. As the extinction is proportional to the dust density and because higher dust densities can be found at smaller scales, one expects more extinction of H$\alpha$ at smaller scales. This leads to a weaker correlation with the radio free–free emission at smaller scales. Hence, it seems
that absorption by dust at scales < 1.2 kpc (Fig. 12, Frick et al. 2001) is less significant in M33 than in NGC 6946. The existence of considerable extinction in NGC 6946 caused by a patchy dust distribution has been shown by Trewella (1998).

8. Summary

Highly resolved and sensitive Spitzer MIPS images of M33 at 24, 70, and 160 µm enabled us to compare the morphology of different dust components of this galaxy. A 2D-wavelet transformation was used to find dominant scales of emitting structures and correlations of the MIPS images with new radio (3.6 and 20 cm) maps as well as with an Hα image of M33. We compared the results of wavelet analysis with and without bright HII regions at different resolutions (18″, 51″, 84″). We found that at a characteristic scale of 210″ or 0.8 kpc, 80% or more of the wavelet energy at 24 and 70 µm and 3.6 cm is from the 11 brightest HII regions. These sources cause better correlations between the scale of the central extended region, < 2.5 kpc (Sect. 7).

- The longer the IR wavelength, the more extended is the distribution of dust grains emitting at that wavelength (Sects. 3 and 4).
- HII regions influence the IR emission with a strength inversely depending on wavelength: more influence at 24 µm and less influence at 160 µm (Sect. 4).
- The nonthermal radio emission correlates well with the thermal radio and Hα emission out to the scale of the central extended region, ~ 2.5 kpc (Sect. 7).
- The warm dust–thermal radio correlation is stronger than the cold dust–nonthermal radio correlation at scales smaller than 4 kpc (about half the size of the galaxy) (Sects. 5 and 7).
- The effect of extinction in Hα is independent of the scale of structures in M33 and is smaller than in NGC 6946.

Acknowledgements. We are grateful to R. Walterbos for kindly providing us with the Hα data. We acknowledge NASA/SSC, University of Minnesota, and University of Arizona for the Spitzer MIPS data. We thank the staff of 100–m Effelsberg telescope and VLA for their assistance with radio observations. The wavelet coefficients were calculated with the program WAVE2D which was written by Igor Patrikeev for MPIfR in 2001-2003. F. Tabatabaei was supported for this research through a stipend from the International Max Planck Research school (IMPRS) for Radio and Infrared Astronomy at the Universities of Bonn and Cologne. RDG, CEW, EP, KDG, JLH, and GHR were supported by NASA/JPL contracts 1256406, 1215746, and 1255094 to the Universities of Minnesota and Arizona.

We thank P. L. Biermann, A. Fletcher, S. Willner, P. Frick, and the anonymous referee for their helpful comments.
