Stellate ganglion block reduces inflammation and improves neurological function in diabetic rats during ischemic stroke

Ting-Ting Li, Qiang Wan, Xin Zhang, Yuan Xiao, Li-Ying Sun, Yu-Rong Zhang, Xiang-Nan Liu, Wan-Chao Yang

Abstract
Diabetes mellitus is an independent risk factor for ischemic stroke. Both diabetes mellitus and stroke are linked to systemic inflammation that aggravates patient outcomes. Stellate ganglion block can effectively regulate the inflammatory response. Therefore, it is hypothesized that stellate ganglion block could be a potential therapy for ischemic stroke in diabetic subjects. In this study, we induced diabetes mellitus in rats by feeding them a high-fat diet for 4 successive weeks. The left middle cerebral artery was occluded to establish models of ischemic stroke in diabetic rats. Subsequently, we performed left stellate ganglion block with 1% lidocaine using the percutaneous posterior approach 15 minutes before reperfusion and again 20 and 44 hours after reperfusion. Our results showed that stellate ganglion block did not decrease the blood glucose level in diabetic rats with diabetes mellitus but did reduce the cerebral infarct volume and the cerebral water content. It also improved the recovery of neurological function, increased 28-day survival rate, inhibited Toll like receptor 4/nuclear factor kappa B signaling pathway and reduced inflammatory response in the plasma of rats. However, injection of Toll like receptor 4 agonist lipopolysaccharide 5 minutes before stellate ganglion block inhibited the effect of stellate ganglion block, whereas injection of Toll like receptor 4 inhibitor TAK242 had no such effect. We also found that stellate ganglion block performed at night had no positive effect on diabetic ischemic stroke. These findings suggest that stellate ganglion block is a potential therapy for diabetic ischemic stroke and that it may be mediated through the Toll like receptor 4/nuclear factor kappa B signaling pathway. We also found that the therapeutic effect of stellate ganglion block is affected by circadian rhythm.

Key Words: circadian rhythms; diabetes mellitus; inflammation; ischemic stroke; long-term prognosis; neurological function; neuron; nuclear factor kappa B; stellate ganglion block; Toll like receptor 4

Introduction
Ischemic stroke and diabetes mellitus (DM) are debilitating conditions with limited therapeutic options. The pathological processes of these two conditions are closely associated; they interact with and exacerbate each other, and both diseases are related to inflammation (Moskowitz et al., 2010; Wei et al., 2016). Encouragingly, anti-inflammatories have shown multiple benefits in both diabetes and stroke (Petrovic-Djergovic et al., 2016; Wattananit et al., 2016; Rayasam et al., 2017). Many studies on inflammation in the treatment of diabetic stroke are now in progress (Petrovic-Djergovic et al., 2016; Wei et al., 2016; Fusco et al., 2019). However, the use of anti-inflammatories during routine clinical perioperative stroke procedures, especially anesthesia, may be limited. Therefore, we aim to identify an approach that is closely related to the treatment of ischemic stroke in diabetic patients.

Stellate ganglion block (SGB) is a unique anesthesia treatment that has a rapid onset, precise effects, minimal side effects and repeatability. It plays an unparalleled role in the treatment of many diseases (Haest et al., 2012; Fisher et al., 2013; Rae Olmsted et al., 2020), significantly reducing the inflammatory response (Yang et al., 2015; Chen et al., 2018). Ultrasound guidance has improved the repeatability. It plays an unparalleled role in the treatment of many diseases (Haest et al., 2012; Fisher et al., 2013; Rae Olmsted et al., 2020), significantly reducing the inflammatory response (Yang et al., 2015; Chen et al., 2018). Ultrasound guidance has improved the effectiveness of SGB in ischemic stroke patients (Yoo et al., 2012; Liu et al., 2020) but there have been few studies on stroke in diabetic patients. These studies suggest that SGB may play an active role in both diabetic and non-diabetic stroke patients.

The Toll-like receptor 4/nuclear factor kappa B (TLR4/NF-κB) pathway is a major inflammatory pathway (Fiorotto et al., 2011) and plays a
Figures 1). All groups were divided into six groups by random number method: Sham (n = 36), middle cerebral artery occlusion (MCAO) (n = 36), SGB daytime (MCAO + SGB; n = 36), SGB night (MCAO + SGBn; n = 12), MCAO + SGB + LPS (n = 18) and MCAO + SGB + TAK242 groups (n = 18). SGB intervention in the MCAO + SGB + LPS and MCAO + SGB + TAK242 groups were the same as that in the SGB daytime group. A dietary and streptozotocin (STZ) induced diabetic rat model was generated in advance and all six-group rats were divided into two models: rats involved in the experiment was in the range 200–280 g.

Materials and Methods

Animals and study design

This study was approved by the Institutional Animal Care Committee of the 2nd Affiliated Hospital of Harbin Medical University, China (approval No. SYDW2019-209) on May 8, 2019. Because there is a higher incidence of strokes in male patients than in females (Ntaios et al., 2017) and estrogen has some neuroprotective effect (Reis de Assis et al., 2021; Willsley et al., 2021), we limited our study to male rats. To reduce other extraneous variables, we used 156 3–4-week-old male clean-level Sprague-Dawley rats weighing 60–80 g that were obtained from the Department of Experimental Animals, Harbin Medical University [license No. SCXK (Hei) 2013-001]. The rats were maintained on a 12/12-hour light/dark cycle at a controlled temperature (21–24°C) and humidity (40–70%) with free access to food and water. All experiments were designed and reported according to the Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines (Peric et al., 2020). Pentobarbital sodium (40 mg/kg; intraperitoneal injection; Siyu, Shanghai, China) was used as an anesthetic before all death surgery in this study.

The rats were divided into six groups by random number method: Sham (n = 36), middle cerebral artery occlusion (MCAO) (n = 36), SGB daytime (MCAO + SGB; n = 36), SGB night (MCAO + SGBn; n = 12), MCAO + SGB + LPS (n = 18) and MCAO + SGB + TAK242 groups (n = 18). SGB intervention in the MCAO + SGB + LPS and MCAO + SGB + TAK242 groups were the same as that in the SGB daytime group. A dietary and streptozotocin (STZ) induced diabetic rat model was generated in advance and all six-group rats were divided into two models: rats involved in the experiment was in the range 200–280 g.

For the diabetic rat model, we induced diabetes mellitus in rats by feeding them a high-fat diet containing 45% fat (10%PUFA, 70% sucrose, 2.5% cholesterol, and 5.7% standard chow (Solarbio; Beijing, China) for 4 weeks (Duca et al., 2015). Next, the rats were given free access to water for one night and received an intraperitoneal injection of streptozotocin (STZ) (35 mg/kg; Sigma-Aldrich (Shanghai) Trading Co., Ltd., Shanghai, China) dissolved in 0.01 M citrate buffer (pH 4.5). After 7 days, we measured the nonfasting plasma glucose levels, and only rats with levels ≥ 11.1 mM were considered sufficiently diabetic to be allocated to experimental groups (Li et al., 2020b). The final weight of the diabetic rats involved in the experiment was in the range 200–280 g.

Middle cerebral artery occlusion model

The MCAO rat model was established as described (Longa et al., 1989). Experimental rats were administered 5% sevoflurane (VETEASY, Shenzhen, China) through a face mask and anesthesia was maintained with 2–3% sevoflurane, allowing spontaneous breathing to continue. After skin preparation and disinfection of the surgical area with alcohol (Chinachem Pharmaceutical Co., Ltd, Shanghai, China) was administered by infiltration for local anesthesia, and a midline incision of approximately 0.5 cm was made at the midpoint between the two ears along the sagittal suture between the parietal bones (Chi et al., 2018). The bregma was identified and defined as the origin of a coordinate system; a cerebral blood flow (CBF) probe was fixed 4 mm left of and 1.5 mm caudal to the bregma, and CBF was monitored by laser Doppler flowmetry (TF5000; PRIMED AB, Stockholm, Sweden). The rats were turned over slowly, and the neck was prepared and disinfected. Local anesthesia was established by infiltration of 1% lidocaine, and a parallel incision was made 3 mm left of the midline. The subcutaneous tissue was separated by blunt dissection with micro-forceps, exposing the left sternocleidomastoid muscle. The digastic, sternocleidomastoid and omohyoid muscles were gradually freed, allowing observation of the left carotid sheath between the muscles. The common carotid artery, external carotid artery and internal carotid artery were separated by blunt dissection. The carotid sheath was making the external carotid artery, and the internal carotid artery was ligated and disconnected, then the proximal end of the common carotid artery and the distal end of the internal carotid artery were clamped with vascular clips. A suture was inserted into the stenosis region of the external carotid artery and the CBF suddenly dropped by more than 70% of the baseline value. The suture was fixed in place and the incision was sutured. The time of suture insertion and the CBF were recorded. The suture was removed from the lumen of the vessel after 90 minutes of embolization. To achieve MCAO-reperfusion (MCAO/R), after the reperfusion, the rats were sent to the animal post-anesthesia care unit, where they were kept warm as they recovered from anesthesia. Additionally, to ensure consistency of the MCAO models in each group, only rats with a Longa score of 2 (Belayev et al., 1996) after model establishment were selected; rats with any other score were excluded from the experiment. MCAO surgery in SGB night group was performed at night.

Stellate ganglion block technique

In this experiment, left SGB was performed using the percutaneous posterior approach after the MCAO model was successfully established (Abdi and Yang, 2005) and slightly adi cardiac artery, no internal carotid artery was disconnected and eco-coagulated, as were the collateral branches of the external carotid artery. The left external carotid artery was ligated and disconnected, then the proximal end of the common carotid artery and the distal end of the internal carotid artery were clamped with vascular clips. A suture was inserted into the stenosis region of the external carotid artery and the CBF suddenly dropped by more than 70% of the baseline value. The suture was fixed in place and the incision was sutured. The time of suture insertion and the CBF were recorded. The suture was removed from the lumen of the vessel after 90 minutes of embolization. To achieve MCAO-reperfusion (MCAO/R), after the reperfusion, the rats were sent to the animal post-anesthesia care unit, where they were kept warm as they recovered from anesthesia. Additionally, to ensure consistency of the MCAO models in each group, only rats with a Longa score of 2 (Belayev et al., 1996) after model establishment were selected; rats with any other score were excluded from the experiment. MCAO surgery in SGB night group was performed at night.

MCAO surgery in SGB night group was performed at night.

Diabetic rat model

We induced diabetes mellitus in rats by feeding them a high-fat diet containing 45% fat (10% PUFA, 70% sucrose, 2.5% cholesterol, and 5.7% standard chow (Solarbio; Beijing, China) for 4 weeks (Duca et al., 2015). Next, the rats were given free access to water for one night and received an intraperitoneal injection of streptozotocin (STZ) (35 mg/kg; Sigma-Aldrich (Shanghai) Trading Co., Ltd., Shanghai, China) dissolved in 0.01 M citrate buffer (pH 4.5). After 7 days, we measured the nonfasting plasma glucose levels, and only rats with levels ≥ 11.1 mM were considered sufficiently diabetic to be allocated to experimental groups (Li et al., 2020b). The final weight of the diabetic rats involved in the experiment was in the range 200–280 g.
Injection of the TLR4 inhibitor TAK242 (3 mg/kg; tail vein injection, N=6/group) was homogenized and centrifuged at 10,000 x g for 20 minutes at 4°C. We collected the supernatants and measured the protein concentrations with a bicinchoninic acid assay kit (Beyotime, Shanghai, China). Then, we separated the protein samples by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred them onto nitrocellulose membranes. The membranes were blocked with 5% milk powder in 0.1% Tris-buffered saline-Tween 20 and incubated with primary antibodies against TLR4 (1:2000; rat; Cat# 35463, RRID: AB_2893499; SAB, City of College Park, MD, USA), NF-kB p65 (rat; 1:2000; Cat# 48500, RRID: AB_2893499; SAB), NF-kB p100 (1:1000; rat; Cat# ab191594, RRID: AB_2893501; Abcam, Cambridge, UK), phospho-NF-kB p65 (phospho-Ser536; 1:2000; RRID: AB_2893502; rat; Cat# YP0191, RRID: AB_2893502; ImmunoWay Technology Company, Plano, TX, USA), and β-actin (1:400; rat; Cat# PR-0255, ZSG Bio, RRID: AB_2636897; Beijing, China) overnight at 4°C. Subsequently, we washed the membranes with 0.1% Tris-buffered saline-Tween 20 and incubated with horseradish peroxidase-conjugated goat anti-rabbit IgG (1:5000; goat; Cat# ZB-2301; RRID: AB_2747412; ZSG Bio) for 1 hour at 25°C. Bands were detected with an electrochemiluminescence kit (Haigene, Shenzhen, China), and a gel imaging system (Clinx Scientific Instruments Co., Ltd, Shanghai, China) was used only for acquisition and analysis.

Results

Western blot analysis

To quantify the protein expression levels of TLR4/NF-κB pathway, at 48 hours after reperfusion, the cerebral cortex (N=6/group) was visualized with an optical microscope (Nikon Eclipse Ti-SR, Tokyo, Japan) at 400x magnification. One section per animal was selected. Images were merged using ImageJ software at the same contrast level.

Measurement of brain water content

To calculate the brain water content: brain water content (%) = (wet weight – dry weight)/wet weight × 100.

Neurological deficits were measured with the modified neurological severity score and the Garcia score on days 1, 3, 5, 7, 14, and 28. The modified neurological severity score (mNSS) and the Garcia score objectively and accurately assess changes in neurological function of rats through a combination of muscle strength, balance, orientation, limb coordination, sensory, and other measures (Chi et al., 2018; Li et al., 2020b). The mNSS score is the sum of all test scores from the tail lift test, grip strength test, back paw test, reflex and paradoxical movement test, with the lowest score 0 and the highest score 18. The higher the score, the worse the neurological function. The Garcia score assesses voluntary movement in the cage for 5 minutes and includes symmetry of limb movement, symmetry of forelimb extension during tail pulling, climbing the cage wall, response to touching the trunk and response to touching the whiskers. The maximum score is 18. The lower the Garcia score, the worse the neurological function. The survival rates were also recorded. Deaths in the Sham, MCAO, SGB daytime and night groups were recorded until day 28, and in the MCAO, MCAO + SGB + LPS and MCAO + SGB + TAK242 groups until 48 hours post MCAO. All rats were exposed to the neurological function testing twice before undergoing surgery. Neurological function scores were conducted by the same investigator, who was blinded to the group assignments. Body weight was monitored daily for 28 days by animal weight scale (Mettler Toledo, Zurich, Switzerland). The weight change (%) was determined relative to the baseline weight (N = 6 rats/group).

Measurement of immunofluorescence

To locate and quantify TLR4 and NF-kB, 48 hours after reperfusion, the rats (N = 6/group) were transcranially perfused with normal saline and 4% paraformaldehyde. The brains were postfixed in 4% paraformaldehyde at 4°C for 24 hours. The infiltrated segments were cut into 10-mm transverse frozen sections. After being washed in 0.2% Triton X-100 for 20 minutes, the sections were blocked with 3% bovine albumin for 30 minutes. The sections were then incubated with primary antibodies against TLR4 (1:100; mouse; Cat# B53489; RRID: AB_1662746; BioWorld Technology, Shanghai, China) and NF-kB (1:200; rat; Cat# BMS-33117M; Bios, Beijing, China) at 4°C overnight and then incubated with fluorescein isothiocyanate isomer-conjugated secondary antibodies (1:1000; goat; Cat# SA00003-2; RRID: AB_2890897; Proteintech, Wuhan, China) for 50 minutes at 25°C. Finally, the sections were incubated with 4’,6-diamidine-2-phenyindole (S192-23-4, Aladdin, Shanghai, China) for 10 minutes and visualized with an optical microscope (Nikon Eclipse Ti-SR, Tokyo, Japan).

Measurement of inflammatory cytokine levels

Results

SGB does not affect the increase in blood glucose level in ischemic stroke rats

The blood glucose level increased significantly between the pre- and post-MCAO measurements. The MCAO group showed rapid blood glucose increase (P < 0.05). Blood glucose after SGB (daytime) also increased (P < 0.05), indicating SGB does not affect the increase in blood glucose resulting from MCAO (Table 1).

Statistical analysis

The sample size was based on our previously reported study (Li et al., 2020b). We used SPSS (version 21.0, IBM, Armonk, NY, USA) statistical software to analyze the data and present the mean ± standard deviation (SD). Two-tailed t-test was used for blood glucose comparison before and after surgery. Multigroup comparisons were performed with one-way analysis of variance followed by the Student-Newman-Keuls test for comparisons brain water content, hemispheric infarct ratio, enzyme-linked immunosorbent assay, western blot and immunofluorescence results. Neurological function scores were analyzed by the Kruskal-Wallis test with Bonferroni correction. Kaplan-Meier survival curves were compared using the log-rank test. Repeated-measures analysis of variance, followed by the least significant difference test, was used for comparisons of 28-day weight change. A P-value < 0.05 was considered statistically significant.
SGB reduces infarct volume and brain water content in ischemic stroke diabetic rats

Forty-eight hours after MCAO, the rats in the MCAO group showed prominent infarct areas and the infarct size was significantly reduced after either day or night SGB treatment (P < 0.05) (Figure 1B and C). Consistent results were obtained for brain water content that was significantly reduced after SGB treatment (Figure 1D).

**Table 2** | Effects of MCAO and SGB on 48-hour survival in rats

| Group          | SGB day | MCAO+SGB+LPS | MCAO+SGB+TAK242 |
|----------------|---------|--------------|-----------------|
| Survive        | 12†     | 12           | 12              |

MCAO: Middle cerebral artery occlusion; mNSS: modified neurological severity scores; SGB: stellate ganglion block.

**Figure 4** | Effect of SGB in the ischemic penumbra of stroke diabetic rats

The TL4 and NF-kB contents were measured by two methods. The localization of the proteins, using immunofluorescence, quantitatively showed that the TL4 content in the ischemic penumbra of ischemic stroke diabetic rats was greatly decreased when treated with SGB (P = 0.0187; Figure 4A). SGB did not reduce the TL4 and NF-kB positive cells when administered 5 minutes after LPS (P = 0.0047; Figure 4A). The results of western blot analysis in the ischemic penumbra showed the greatest significant difference (MCAO group vs. SGB daytime group: P < 0.0001; Figure 4B). Immunofluorescence indicated that NF-kB was present mainly in the nucleus in the MCAO group, possibly because nuclear translocation of NF-kB was enhanced in the MCAO group. The western blot results showed that NF-kB p65 phosphorylation was enhanced in the MCAO group, while SGB inhibited this phosphorylation (P = 0.0022). No significant differences in NF-kB p100 phosphorylation were observed, except between the SGB daytime and the MCAO + SGB + TAK242 groups. NF-kB p100 expression in the MCAO + SGB + TAK242 group was significantly lower than that in the SGB daytime group (Figure 4B).
SGB inhibits the inflammation in plasma of ischemic stroke diabetic rats

Compared with SGB daytime group, the TNF-α level in SGB night group was significantly lower (P < 0.0001; Figures 5A) but there were no significant differences in the IL-6 levels between the day and night groups (P = 0.078; Figures 5A). The IL-1β and TNF-α levels in the SGB daytime group were lower than those in the MCAO group (IL-1β: P < 0.0001; TNF-α: P < 0.0001; Figure 5B). Compared with those in the SGB daytime group, the IL-1β and TNF-α levels were greatly reduced in the MCAO + SGB + TAK242 group (IL-1β: P < 0.0001; TNF-α: P < 0.0001; Figure 5B) and greatly increased in the MCAO + SGB + LPS group (IL-1β: P = 0.0006; Figure 5B).

Discussion

This study has shown that SGB can effectively improve long-term neurological function after ischemic stroke in diabetic rats and that the mechanism involves the TLR4/NF-κB pathway. We also observed diurnal differences in the effect of SGB treatment.

This experiment used a diabetic rat MCAO model. Diabetes has a high prevalence and is a risk factor for ischemic stroke. The mortality and long-term adverse outcome rates of patients with diabetes are significantly higher than those of the general population (O’Donnell et al., 2018; GBD 2017 Disease and Injury Incidence and Prevalence Collaborators, 2018; Lo et al., 2020). Moreover, the primary method of clinical perioperative preparation is still controlling glycemia, but a significant multicenter data study found that merely controlling the blood sugar level after a stroke cannot effectively improve the long-term neurological function of diabetic patients (Lo et al., 2020). Therefore, it is particularly important to find an effective perioperative stroke control method for diabetic stroke patients. This experiment used a diabetic rat MCAO model to study a potential perioperative stroke control method for diabetic stroke patients. This experiment used a diabetic rat MCAO model to study a potential perioperative stroke control method for diabetic stroke patients.
rat model, and blood glucose monitoring was continued after the modeling was completed to eliminate the possibility that the blood glucose level was neither too high nor too low enough to affect the survival of the MCAO rats.

In experiments with rats as subjects, the commonly used methods of SGB include surgical exposure (cervical sympathetic nerve trunk transection, stellate ganglion catheterization, or direct injection of medicine) and percutaneous injection (anterior approach, posterior approach, or lateral approach) (Iwama, 1997; Abdi and Yang, 2005; Gulcu et al., 2009; Chen et al., 2012). The surgical exposure, percutaneous pre-injection approach and percutaneous injection side approach have certain limitations, including inevitably causing tissue damage, infection, and increased possibility of mortality of the subject. The posterior percutaneous approach does not have these limitations, including no tissue trauma, little bleeding and the process is simple and has good repeatability. Thus, the posterior percutaneous approach was used to perform SGB in rats in this experiment. However, there are other potential complications resulting from SGB, including hematomata, brachial plexus injury, phrenic nerve block and pneumothorax. The use of ultrasound-guided technology for the operation can significantly reduce potential complications.

Our data indicate that SGB has an excellent therapeutic effect on the acute phase of ischemic stroke in diabetic rats. The recovery of stroke is generally assessed primarily over the following weeks and months (Shih et al., 2015). Therefore, clinical improvement after intervention should also be evaluated over a relatively long observation period. Our study showed that the long-term functional advantages of SGB are very clear, and these results comprehensively demonstrated the beneficial effect of SGB on long-term (28-day) neurological outcomes and weight recovery in diabetic rats. However, we also observed a high poststroke mortality rate in diabetic rats that far exceeded that indicated in clinical data. This high mortality rate may be linked to the blood glucose level in the rat model. In our study, rats with blood glucose over 25 mM had much higher mortality rates than other diabetic rats, which did correlate with their significantly higher postoperative blood glucose levels (higher than 33 mM). To prevent the influence of blood glucose levels in this study, we limited the blood glucose level of diabetic rats to a range of 15–25 mM. It had been shown that nutritional support (dry granules on the cage floor, jelled food administered orally, and jelled food provided in Petri dishes), starting on the second day after MCAO, reduced the 14-day mortality rate from 59% to 15% (Chi et al., 2018). However, in our experiments, rats merely had free access to food and water after surgery and did not receive additional nutritional support.

We explored the TLR/NF-κB pathway to better explore the molecular mechanism through which SGB improves long-term neurological function after ischemic stroke. Our study showed that SGB treatment reduced the level of NF-κB p65 (p65) phosphorylation and decreased NF-κB translocation. This activity generally refers to translocation of p65 from cytoplasm into nucleus after phosphorylation. We measured phosphorylated p65 (p-p65) and total p65, which showed inhibition of p-p65 after SGB. In addition, immunofluorescence showed some of the p65 overlapped with total p65, which showed inhibition of p-p65 after SGB. In addition, immunofluorescence showed some of the p65 overlapped with nuclei, both western blot and immunofluorescence measurements indicated that SGB was related to the transfer of NF-κB p65 to the nucleus. During this process, it was found that the level of IL-6 increased rapidly after infection and peaked at 2 hours (Fraunberger et al., 2006; Abe et al., 2010). However, our study found that the level of IL-6 had not changed significantly when we measured it 48 hours after MCAO. Therefore, we probably missed the peak level of IL-6 and that by 48 hours it had returned to base levels. A recent study found that the difference in circadian rhythms is one reason responsible for the mortality rate in rodent stroke models frequently cannot translate to clinical research (Esposito et al., 2020). We found SGB in rats exhibited diurnal variation. Interestingly, daytime administration of SGB was effective in improving ischemia and long-term neurological function, promoting weight recovery, reducing mortality, and reducing inflammation. However, nighttime SGB was not effective in improving ischemia and long-term neurological function and weight recovery. Although SGB could not improve ischemia and long-term neurological function and weight recovery, the results indicate that SGB may be an effective way to reduce sympathetic nerve activity. In contrast to the circadian rhythm of rats, studies with patients suggest that the best time for SGB was at night. We think SGB could be useful in reducing daytime sympathetic overexcitability. This hypothesis also provides a theoretical basis for precision application of SGB and the optimization of treatment plans for clinical patients. Conversely, we found that the agonist LPS can markedly activate inflammation-related pathways, leading to a high mortality rate in the MCAO + SGB + LPS group of diabetic rats.

Compared with previous experiments, our experiment has the following innovations. First, we studied the effect of SGB in this compound model, which is highly important for the development of the field. Second, no study has addressed circadian rhythms in SGB. This study provides a new concept and theoretical basis for using SGB to optimize relevant treatment measures in clinical applications. Although the positive effects of SGB for stroke have been known since 1947 (Risteen and Volpitto, 1946), subsequent studies have focused on the effectiveness of SGB in relieving pain in patients with subacute stroke with complex localized pain syndrome. Recent studies have shown that SGB has a therapeutic effect on post-stroke pain that had failed to respond to pharmacological treatment. However, our study focused on the perioperative neuroprotection and prognosis of diabetic stroke, which was not only more comprehensive, but also innovative in studying the effect of SGB on two compound diseases. Previous studies on SGB were relatively simple, but our research explored SGB at the molecular and mechanistic levels, adding clarity and accuracy to the mechanism of SGB. Finally, we identified the optimum range for blood glucose control. When the blood glucose level was controlled 25.0 mM, the mortality rate of the MCAO model increased significantly; this observation can be a reference for related basic research. In addition, we found that the ear capillaries of some rats were dilated after SGB.

Our research also has certain limitations. The ischemia time selected in this study was 90 minutes, which is the time window from the onset of the disease to recanalization treatment for most hospitalized patients based on our observations. However, in clinical practice, some patients are treated within a different time window. In addition, the SGB effect is a minimally invasive blocking technique that can be implemented only by skilled anesthesiologists.

In conclusion, SGB is effective in improving long-term neurological outcomes and quality of life after ischemic stroke in diabetic rats and demonstrates that the mechanism is related mainly to specific inhibition of TLR4/NF-κB pathway activation. The SGB treatment is also influenced by circadian rhythms; thus, proper timing of treatment is important. SGB is widely used in various clinical diseases. However, this study provides a precise optimization strategy for the perioperative period before and after reperfusion when surgical treatment is performed on diabetic patients that suffered an ischemic stroke.

Author contributions: Material preparation, data collection and analysis: TTL, QW, XZ, YX, LYS, YRZ, XNL; manuscript draft: TTL; manuscript revision: YRZ, XNL; final approval: TTL, QW, XZ, YX, LYS, YRZ, XNL; manuscript drafting: TTL; manuscript review: WCY. All authors contributed to the conception and design of the study, and commented on previous versions of the manuscript. All authors read and approved the final manuscript.

Conflicts of interest: The authors declare that they have no conflicts of interest.
