Urinary output and fractional excretion of sodium and urea as indicators of transient versus intrinsic acute kidney injury during early sepsis

Jill Vanmassenhove1, Griet Glorieux1, Eric Hoste2,3, Annemieke Dhondt1, Raymond Vanholder1 and Wim Van Biesen1*

Abstract

Introduction: The pathophysiology of acute kidney injury (AKI) in sepsis is ill defined. We investigated parameters associated with low glomerular filtration, and their predictive value to discriminate transient from intrinsic septic AKI.

Methods: In 107 sepsis patients, AKI was defined by the Risk, Injury, Failure, Loss of Kidney Function, End-stage renal disease (RIFLE) urinary output or serum creatinine criterion, or both. Transient AKI (TAKI) versus intrinsic AKI was defined as RIFLE R, I, or F on the first day evolving to no AKI or not, respectively, over the following 5 days. Fractional excretion of sodium (FENa), urea (FEUrea), and NGAL (FENGAL) at admission (d0t0), 4 (d0t4), and 24 hours (d1) was determined.

Results: Including versus not including the urinary-output criterion of RIFLE increased AKI from 43% to 64.5%. Median uNGAL levels and FENGAL were lower in no AKI versus transient AKI when AKI was defined based on creatinine (P = 0.002 and P = 0.04, respectively), but not when based on urinary output (P = 0.9 and P = 0.49, respectively). FENa < 1% and FEUrea <35% was present in 77.3% and 63.2% of patients. Urinary NGAL was higher (P < 0.001) in those with high versus low fractional sodium excretion, but this was only in patients with transient or intrinsic AKI (P < 0.001 in subgroups), and not in patients without AKI. The negative predictive value for either intrinsic AKI or not restoring diuresis in patients with FENa > 0.36% and FEUrea > 31.5% was 92% and 94.5% respectively.

Conclusions: A low FENa and FEUrea is highly prevalent in the first hours of sepsis. In sepsis, oliguria is an earlier sign of impending AKI than increase in serum creatinine. A combination of a high FENa and a low FEUrea is associated with intrinsic AKI, whereas a combined high FENa and FEUrea is strongly predictive of transient AKI.

Introduction

Controversy exists about the role of low glomerular filtration pressure in the pathogenesis of septic acute kidney injury (AKI) [1-3]. Tubular damage due to inflammatory cascades is also proposed as a potential underlying pathophysiological mechanism [4-7]. Recently, it was demonstrated that transient azotemia can be more than a physiologic response to low glomerular filtration pressure, as it can also be associated with transient low-grade tubular injury, as defined by the presence of neutrophil gelatinase-associated lipocalin (NGAL) [8] or liver fatty acid binding protein (LFABP) [9]. Whereas these findings enhance our understanding of the pathophysiology of AKI, they are not always very helpful in clinical practice, in which the most important dilemma is to differentiate those cases in which restoration of glomerular filtration pressure can potentially still reverse AKI from those in which it will lead only to fluid overload. This is important, as increasing evidence links blind fluid loading to higher mortality [10,11].

Although most definitions of AKI are based on both an increase in serum creatinine and a decrease in urinary output, the latter criterion has been neglected in many studies [12-15]. Recent work has demonstrated that urinary output is important, as it is associated with morbidity and mortality [16]. A low urinary output can be used as an early-warning parameter of developing AKI, maybe even before tubular damage arises.

We hypothesized that the combined interpretation of a reduced urinary output, and a low fractional excretion of sodium and urea, and especially the evolution of these parameters, is an early indicator of incipient AKI in sepsis patients, when it is still reversible if glomerular...
filtration pressure is restored. We also hypothesized that a high fractional sodium excretion can be an indicator of active sodium secretion by damaged tubular cells and reduced proximal tubular reabsorption, whereby extent of tubular damage was assessed by (fractional excretion of) urinary neutrophil gelatinase-associated lipocalin (NGAL).

Materials and methods
The study was approved by the ethical committee of the Ghent University Hospital. Written informed consent was obtained from the patients or their next of kin.

In total, 107 consecutive patients with sepsis admitted to the intensive care unit (ICU) of a tertiary university hospital were included between 12/01/2010 and 5/09/2010. Sepsis, severe sepsis, and septic shock were defined according to the American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference guidelines [17]. Exclusion criteria were (a) a history of liver and/or kidney transplantation, (b) ICU stay less than 24 hours, (c) patients treated with chronic hemodialysis, and (d) age younger than 17 years.

Acute kidney injury (AKI) was defined according to RIFLE classification (Risk, Injury, Failure, Loss of kidney function, and End-stage renal disease) [13]. Baseline creatinine was based on the most recent value before admission or was calculated if the latter was not available [13]. The urinary-output criterion was based on 6-hour blocks, as described by Macedo et al. [16]. As we wanted to assess the impact of the creatinine and the urine output criteria separately, we defined AKI based on both criteria (AKIboth) together, versus on the urinary output criterion alone (AKIuo), or the serum creatinine criterion alone (AKIc).

Transient AKI (TAKI) was defined as RIFLE R, I, or F on day 1 that improved to “no AKI” in the following 5 days, whereas “intrinsic AKI” was defined as patients with RIFLE R, I, or F who did not evolve to “no AKI” in the following 5 days.

Urine and blood samples were collected at the moment of admission (time point d0t0), and also 4 hours later (time point d0t4) and 24 hours later (time point d1), to assess the evolution of the parameters. Blood samples were centrifuged within 20 minutes after collection at 1,500 g for 10 minutes, and serum was aliquoted and stored at −80°C for later batch analysis. Urine was collected in a sterile way and centrifuged at 500 g for 10 minutes; urine samples were aliquoted and stored at −80°C for later batch analysis.

Serum and urinary neutrophil gelatinase-associated lipocalin (NGAL) were measured by using an ELISA kit (Gentofte (Denmark) Bioponto Diagnostics).

Fractional excretion of sodium, urea, and NGAL was calculated according to the formula (Ux × Screa)/(Ucrea × Sx) × 100 with x = either sodium, urea, or NGAL. Patients were classified according to FEUrea and FENa quartiles. We also defined FENA and FEUrea dichotomously as “high” (two upper quartiles) and “low” (two lower quartiles).

Statistical analysis
Results are reported as medians and interquartile ranges (IQRs) for continuous variables, unless otherwise specified. Discrete variables are reported as numbers and/or percentages. All statistical analyses were performed by using SPSS 19. All consecutive patients were included, irrespective of their course or duration of stay at the ICU.

Continuous variables were compared between groups by using the Mann–Whitney U test (two groups) or the Kruskal-Wallis (more than two groups), as appropriate, by using the nonparametric section of SPSS 19. When the overall P value was <0.05, post hoc analysis between different pairs was performed by using Mann–Whitney U tests, taking into account correction for multiple testing.

Dichotomous variables in groups were compared by using χ² analysis. Positive and negative predictive values were calculated for high and low fractional excretion of sodium and urea, whereby “high” and “low” were based on the median value. We performed Receiver Operating Characteristic (RoC) curves to assess the performance of fractional excretion of sodium and urea to predict transient or intrinsic AKI.

Performance of the combined interpretation of fractional excretion of sodium and urea was evaluated by calculating positive and negative predictive power of the different combinations for restoration of diuresis and for development of intrinsic AKI.

Results
In total, 107 consecutive patients were included. Demographic and clinical data are shown separately for AKI versus no-AKI patients, as defined by RIFLE on the first day of admission (Table 1). Demographic and clinical data for no-AKI versus transient AKI versus intrinsic AKI are shown in Table 2. Based on both RIFLE criteria combined (AKIboth), 35.5% of patients had no AKI, and 20.6%, 31.8%, and 12.1% had RIFLE R, I, and F. When AKI was defined based on urinary output alone (AKIuo), 58.9% of patients were classified as having no AKI, and 10.3%, 27.1%, and 3.7% had RIFLE-R, I, and F respectively. When defining AKI based on the creatinine criterion alone (AKIc), 57% had no AKI, and 17.8%, 15%, and 10.3% were classified as RIFLE R, I, and F (Figure 1), so omitting the urinary-output criterion leads to underdiagnosis of AKI.

Upper cut-off values for the FENA quartiles based on the values of d0t0 were 0.15%, 0.36%, and 0.95%. At time points d0t0, d0t4, and d1, 77.3%, 74.5%, and 71.1% of
patients had a fractional excretion of sodium (FENa) <1%, the currently used cut-off value.

Upper cut-off values for the FEUrea quartiles were 21%, 31.5%, and 42.0%. At time points d0t0, d0t4, and d1, 63.2%, 50.9%, and 41.3% of patients had a fractional excretion of urea (FEUrea) <35%.

There was a stepwise increase in prevalence of AKI based on urinary output, with quartiles of decreasing FENa and FEUrea at d0t0 \( (P = 0.05 \text{ and } P = 0.01) \) and d0t4 \( (P < 0.001 \text{ for both}) \), but not at d1 for FENa \( (P = 0.18) \). No such association was noted for AKI based on creatinine (Table 3).

The values for FENa and FEUrea in the different AKI stages based on urinary output are illustrated in Figure 2A and B, respectively. FENa was <1% in the majority of patients at all time points, except in patients classified as F at timepoint d1, where the median was 2.16%. A U-shaped pattern of FENa was seen over the different AKI stages based on urinary output \( (P = 0.07, 0.016, \text{ and } 0.01 \text{ at d0t0, d0t4, and d1, respectively}) \) (Figure 2A). There was a decreasing trend in FEUrea at d0t0, d0t4, and d1 across different AKI stages based on urinary output (Figure 2B). Patients with stage F AKIuo

### Table 1 Clinical and demographic characteristics of the study cohort comparing patients without versus those with AKI, as defined by RIFLE on the first day of admission

|                        | No AKI \((n = 38)\) | AKI \((n = 69)\) | \(P\) value |
|------------------------|---------------------|-----------------|-------------|
| Gender male (%)        | 57.9                | 55.1            | 0.78        |
| Age (years, mean/SD)   | 57.5 (16.0)         | 62.7 (14.2)     | 0.09        |
| CKD on admission (MDRD <60 ml/min/1.73 m\(^2\)) (%) | 10.5 | 8.7 | 0.76 |
| APACHE II score on the first day of admission | 21 (10) | 23 (9) | 0.19 |
| Positive fluid balance first 24 hours (mean/SD) | 2.5 (2.1) | 4.0 (2.3) | 0.002 |
| Use of diuretics on the first day of admission (%) | 18.4 | 17.4 | 0.89 |
| RRT need during ICU stay (%) | 5.3 | 17.4 | 0.08 |
| Vasopressor use (%)    | 42.1                | 68.1            | 0.009       |
| Total dose of noradrenaline first 24 hours (μg/kg/min) | 0.15 (0.25) | 0.13 (0.20) | 0.83 |
| Maximum dose of noradrenaline during first 24 hours (μg/kg/min) | 0.32 (0.44) | 0.34 (0.51) | 0.83 |
| Need for ventilation during ICU stay (%) | 59.4 | 59.4 | 0.23 |
| ICU mortality (%)      | 21.1                | 27.5            | 0.46        |
| Mortality at 90 days (%) | 26.3 | 36.2 | 0.30 |

### Table 2 Clinical and demographic characteristics of the study cohort comparing patients with no AKI versus transient AKI versus intrinsic AKI

|                        | No AKI \((n = 28)\) | Transient AKI \((n = 57)\) | Intrinsic AKI \((n = 22)\) | \(P\) value |
|------------------------|---------------------|-----------------------------|-----------------------------|-------------|
| Gender male (%)        | 51.7                | 54.4                        | 59.1                        | 0.93        |
| Age (years, mean/SD)   | 55.4 (17.3)         | 62.6 (13.3)                 | 63.1 (14.9)                 | 0.08        |
| CKD on admission (MDRD <60 ml/min/1.73 m\(^2\)) (%) | 10.7 | 8.8 | 9.1 | 0.96 |
| APACHE II score on the first day of admission | 21 (10) | 22 (8) | 24.5 (9) | 0.08 |
| Positive fluid balance first 24 hours (mean/SD) | 2.2 (1.8) | 3.3 (1.9) | 5.4 (2.7) | <0.001 |

| RRT need during ICU stay (%) | 0 | 1.8 | 59.1 | <0.001 |
| Vasopressor use (%)    | 32.1                | 61.4                        | 86.4                        | <0.001      |
| Total dose of noradrenaline first 24 hours (μg/kg/min) | 0.13 (0.22) | 0.12 (0.19) | 0.16 (0.28) | 0.66 |
| Maximum dose of noradrenaline during first 24 hours (μg/kg/min) | 0.28 (0.34) | 0.32 (0.47) | 0.49 (0.68) | 0.66 |
| Need for ventilation during ICU stay (%) | 39.3 | 50.9 | 86.4 | 0.003 |
| LOS (days)             | 39.3                | 5 (10)                      | 38 (32)                     | 0.014       |
| ICU mortality (%)      | 21.4                | 15.8                        | 54.2                        | 0.002       |
| Mortality at 90 days (%) | 28.6 | 24.6 | 59.1 | 0.012 |
had a persistent FEUrea <20% at the three time points (Figure 2B).

To analyze the discriminative power of fractional excretion of sodium and urea and of urinary NGAL to discriminate transient and intrinsic AKI, we performed receiver operating characteristic curves, yielding areas under the curves of 0.59, 0.36, and 0.67, respectively, pointing out that none of these parameters had sufficient power to discriminate intrinsic from transient AKI.

We wanted to assess the predictive value of a combined interpretation of fractional excretion of sodium and urea for the evolution of diuresis and AKI.

Table 3 Prevalence of AKIuo and AKIc (percentage of all patients classified in that category) in different FENa and FEUrea quartiles

| FENa quartiles | AKIuo d0t0 $P = 0.05$ | AKIuo d0t4 $P < 0.001$ | AKIuo d1 $P = 0.18$
|----------------|-----------------------|------------------------|------------------|
| <0.15          | 57.7                  | 72.4                   | 53.3             |
| 0.15-0.36      | 48.1                  | 34.6                   | 46.7             |
| 0.36-0.95      | 33.3                  | 39.1                   | 33.3             |
| >0.95          | 23.1                  | 14.3                   | 28.1             |

| FEUrea quartiles | AKIuo d0t0 $P = 0.01$ | AKIuo d0t4 $P < 0.001$ | AKIuo d1 $P = 0.01$
|------------------|-----------------------|------------------------|------------------|
| <21              | 59.3                  | 77.8                   | 83.3             |
| 21-31.5          | 48.1                  | 55.5                   | 38.1             |
| 31.5-42          | 37.5                  | 22.2                   | 30               |
| >42              | 17.9                  | 23.5                   | 34.1             |

| FENa quartiles | AKIc d0t0 $P = 0.76$ | AKIc d0t4 $P = 0.66$ | AKIc d1 $P = 0.09$
|----------------|----------------------|----------------------|------------------|
| <0.15          | 34.6                 | 37.9                 | 33.3             |
| 0.15-0.36      | 40.7                 | 46.2                 | 40               |
| 0.36-0.95      | 48.1                 | 34.8                 | 29.6             |
| >0.95          | 46.2                 | 50                   | 59.4             |

| FEUrea quartiles | AKIc d0t0 $P = 0.06$ | AKIc d0t4 $P = 0.17$ | AKIc d1 $P = 0.72$
|------------------|----------------------|----------------------|------------------|
| <21              | 55.6                 | 61.1                 | 33.3             |
| 21-31.5          | 51.9                 | 44.4                 | 33.3             |
| 31.5-42          | 20.8                 | 44.4                 | 46.7             |
| >42              | 39.3                 | 29.4                 | 43.9             |

$P$ values represent $\chi^2$ over the quartiles.
Therefore, a categoric representation of percentages of patients with no AKI, transient AKI, and intrinsic AKI in different subgroups of high and low fractional excretion of sodium and urea at 4 hours is cross-tabulated in Table 4 (A, based on urinary output: $P < 0.001$; B, based on creatinine: $P = 0.01$; C, based on both urinary output and creatinine: $P < 0.001$). The negative predictive value for intrinsic AKI for patients with both high fractional excretion of sodium and urea was 92.0%; the negative predictive value that urinary output would not restore in patients with this combination was 94.9%. In contrast, the positive predictive value of a high fractional sodium excretion in combination with a low fractional urea excretion for persisting oliguria was 54%. Thus, a high fractional sodium and a urea excretion are nearly always associated with transient AKI and restoration of diuresis, whereas in patients with a high fractional sodium excretion in combination with a low fractional urea excretion, there is substantial risk for persisting oliguria. The same evaluation for the same parameters at admission showed the same trend (data not shown).

Urinary NGAL values at 4 hours in patients with no AKI, transient AKI, and intrinsic AKI are represented in Figure 3, and this separately for AKI defined on urinary output (Figure 3A), on creatinine (Figure 3B), or both criteria (Figure 3C) ($P$ value overall < 0.001). In post hoc analysis, a difference in median NGAL levels occurred between no AKI and transient AKI when AKI was defined based on creatinine ($P = 0.002$) whereas there was no difference when it was based on urinary output.

**Table 4 Cross-tabulation of FENa <0.36%/FEUrea <31.5% versus FENa >0.36%/FEUrea <31.5% versus FENa <0 36%/FEUrea >31.5% versus FENa >0.36%/FEUrea >31.5% in AKIuo (A), AKIc (B), and AKIboth (C)**

AKIuo, AKIc, AKIboth: Acute kidney injury based on urinary output (uo), serum creatinine (c), or both criteria (both).
A: $P < 0.001$, B: $P = 0.01$ and C: $P < 0.001$. 
A similar gradual increase occurred in the fractional excretion of NGAL in no-AKI versus transient AKI ($P = 0.04$) versus intrinsic AKI ($P = 0.001$) when AKI was defined based on the creatinine criterion but again, there was no significant difference between no-AKI and transient AKI ($P = 0.49$) when AKI was defined according to the diuresis criterion only (graphic illustration similar to Figure 3; not shown).

Urinary NGAL levels and fractional excretion of urea in patients with no AKI versus transient versus intrinsic AKI, and separately for those with a fractional sodium excretion below or above 0.36% are depicted in Figure 4A and B, respectively. Median urinary NGAL was higher in the overall group in those with high (>0.36%) versus low (<0.36%) fractional sodium excretion (median, 1,005 versus 314 μg/g creatinine, respectively; $P 0.025$). In those with high fractional sodium excretion (>0.36%), urinary NGAL was higher in those with intrinsic AKI versus those with transient AKI (median, 4,146 versus 1,544 μg/g creatinine; $P = 0.001$). In those with a low fractional sodium excretion <0.36%, the difference was not significant (917 versus 286 μg/g creatinine; $P = 0.29$) (Figure 4A). Median fractional excretion of urea was higher (39.6% versus 28.6%; $P = 0.02$) in the overall group in those with high (>0.36%) versus low (<0.36%) fractional sodium excretion. In those with high fractional sodium excretion (>0.36%), fractional urea excretion was lower in those with intrinsic AKI versus those with transient AKI (28.8% versus 38.7%; $P = 0.04$). An RoC analysis of fractional urea excretion in patients with a fractional sodium excretion >0.36% yielded an AUC of 0.76 for discrimination between transient and intrinsic AKI. In those with
a low fractional sodium excretion <0.36%, the difference was not significant (21.6% versus 27.6%; \( P = 0.49 \)) (Figure 4B).

The median volume of HES administered in no-AKI versus transient AKI based on urinary output was 0.5 L versus 0.53 L (\( P = 0.15 \)). Based on the creatinine criterion, this was 0.5 L and 0.5 L in no-AKI versus transient AKI (\( P = 0.64 \)).

Discussion
When urinary output was used on top of serum creatinine in this cohort of sepsis patients to define AKI, more cases of AKI were detected as compared with when AKI was based on only the creatinine criterion. More important, transient AKI based on the RIFLE urinary output criterion was not associated with tubular damage as assessed by urinary NGAL, whereas tubular damage was found when diagnosis of transient AKI was based on the RIFLE creatinine criterion. Our data indicate that in patients with incipient sepsis, FENa is far below the proposed cut-off of 1%, which might explain the poor performance of the FENa < 1% criterion. Unexpectedly, a persisting very low fractional urea excretion <31.5% was associated with intrinsic rather than transient AKI. A combined interpretation of high fractional sodium and urea excretion yielded a high negative predictive value for intrinsic AKI (92%) and persisting oliguria (95%), whereas a high fractional sodium and low fractional urea excretion had a 54% positive predictive value for patients remaining oliguric or developing intrinsic AKI.

Progress in the field of acute kidney injury has been hampered by lack of a uniform definition. In the last decade, several recommendations for a consensus definition have been proposed [13-15]. However, although all these definitions are based on both serum creatinine and urinary output criteria together, the latter parameter has been neglected in many studies. This is mainly because urinary output is mostly not available in administrative databases, or because people believe it is difficult to register urinary output. As a consequence, ongoing debate exists on the value of urinary output for defining AKI [18-23]. However, oliguria is also associated with hard outcomes, such as mortality [24], so it is now stressed that urinary output also should be taken into account when classifying AKI [15]. In our cohort, prevalence of the diagnosis of AKI decreased from 64.5% to 43% when urinary output was not taken into account. Whereas patients with transient AKI based on urinary output had similar levels of urinary NGAL production as did patients without AKI, patients with transient AKI based on creatinine had levels of urinary NGAL production intermediate between no AKI and intrinsic AKI (Figure 3), in line with the findings of Nejat et al. [8], where only the creatinine criterion was used. These results were confirmed when the fractional excretion of NGAL was used instead of urinary NGAL alone. These findings underline the concept that an increase in creatinine lags behind for early diagnosis of AKI, and that making a diagnosis based on urinary output might increase the potential for intervention at a stage when no tubular damage yet exists.
Recently it was demonstrated in a post hoc analysis of the Chest study that fluid resuscitation with HES versus saline was more favorable when AKI was defined according to the diuresis criterion only, whereas saline was more favorable than HES when AKI was defined according to the creatinine criterion only [25]. In our cohort, the volume of HES administered was not different between no AKI and transient AKI and between transient AKI based on the diuresis criterion versus transient AKI based on the creatinine criterion.

Recently, it was demonstrated that assessment of urinary output can be easily and accurately achieved by registering it in 6- to 8-hour blocks [16]. This approach would make it possible even to monitor urinary output in patients without an indwelling bladder catheter, and maybe even outside the intensive care unit, at the hospital ward. This would be of importance, as it has been demonstrated that the majority of (fatal) cases of AKI develop unnoticed on the ward and are diagnosed with much delay [26].

There is discussion on the discriminatory value of fractional sodium excretion for the diagnosis of transient AKI. Usually, a cutoff of <1% is suggested as a diagnostic discriminant [27-29]. Our data indicate that this cutoff might be far too high, at least in sepsis, as 75% of the patients in our cohort had FENa <1%, and 50% even had a value <0.36%. Bagshaw et al. [30] recently reported an admission FENa below 1% in 57% of sepsis patients, being not different from nonsepsis patients. Darmon et al. [31] reported a median FENa on admission of 0.50%. Using RoC curve analysis, the same authors also found that a fractional excretion of 0.58% had the best discriminative power, resulting in a positive and negative predictive power for persistent AKI of 0.71 and 0.47, respectively [31]. In our cohort, we used the median, being 0.36%.

Our data highlight some other pitfalls for the interpretation of a high fractional sodium excretion. First, a high fractional excretion of sodium can also be a marker of tubular damage, due to active tubular secretion and reduced proximal tubular reabsorption. In our cohort, potentially in line with presumed tubular damage, we indeed found higher urinary NGAL levels in patients with a high versus low fractional sodium excretion, and this was most expressed in those who develop intrinsic AKI. Interestingly, in our cohort, patients with transient AKI had only higher urinary NGAL levels when they also had high fractional excretion of sodium >0.36% (Figure 4A), suggesting that some patients with transient AKI indeed develop some (minor) degree of tubular damage, whereas others do not. This also underpins that an increase in fractional sodium excretion is not always a positive sign, but can also be an indicator of subclinical tubular damage, which further adds to the low discriminative power of fractional sodium excretion, even when assessed in consecutive samples.

Second, a high fractional excretion of sodium might be caused by interference with use of diuretics. In our cohort, only a minority of patients were treated with diuretics, and those were equally distributed between AKI and no AKI. De Witte et al. [32] found much higher values of fractional sodium excretion in their cohort, but only a minority of their patients had sepsis, whereas 60% were treated with diuretics. Because of these two reasons, a high FENa can thus not be interpreted by itself.

Third, although the fractional excretion of sodium mainly decreases because of reduced urinary output and stimulation of sodium reabsorption, it can be speculated that fractional excretion of sodium also decreases when glomerular filtration decreases (for example, because of tubular obstruction). Therefore, although in our cohort, a very low fractional sodium excretion below <0.36% yielded a negative predictive value for intrinsic AKI of 87.3%, it is probably not a strong discriminative parameter, as was also suggested by Darmon et al. [31].

Surprisingly, and against our initial hypothesis, a low (<31.5%) fractional urea excretion at 4 hours was associated with intrinsic rather than with transient AKI, especially when it was persistent over time, whereas a value higher than 31.5% had a very high negative predictive value for intrinsic AKI. In patients with a fractional sodium excretion above 0.36%, the discriminatory value of fractional urea excretion was even more pronounced (Figure 4B).

Darmon et al. [31] reported an FEUrea of 39% in the no-AKI versus 41% in the transient AKI versus 32% in the intrinsic AKI group, and concluded that FEUrea had a low value for discriminating intrinsic AKI. They based their analysis on admission FEUrea, whereas we used the value 4 hours after admission, when some attempts to restore low glomerular filtration pressure (for example, by a fluid challenge or start of vasopressors) have already been installed. However, data based on FEUrea and FENa at admission showed comparable results, although less impressive (data not shown). Our findings are in line with those of De Witte et al., who also found a reasonable value of FEUrea <40% as a parameter to discriminate transient from intrinsic AKI [32]. As a low fractional excretion of urea apparently represents a low glomerular filtration, we hypothesized that a combination of fractional sodium and urea excretion would yield the optimal prediction of patients with a substantial chance to respond positively to attempts to restore glomerular filtration. Indeed, in our cohort, a combination of a high fractional sodium and urea excretion yielded a 95% probability of restoring diuresis, and the AKI being transient rather than intrinsic, whereas a persistently low fractional urea excretion in
combination with a high fractional sodium excretion was suggestive for intrinsic AKI.

Debate exists on the discriminatory value of NGAL to predict or diagnose AKI in clinical conditions, as much overlap in NGAL levels is seen between patients with versus without AKI [33]. NGAL is a 25-kDa molecule that is filtered into the primary urine at the glomerular level. In sepsis, serum levels of NGAL increase exponentially [34,35], even in the absence of AKI [36], which can result in increased urinary levels as well [37]. Once filtered, NGAL is reabsorbed by the tubular epithelium through the megalin receptor, and this through competitive binding [38].

Although a recent study indicated that urinary NGAL stems from local production in the thick ascending limb of the loop of Henle when stress factors are applied, evidence suggests that urinary NGAL can derive from the systemic circulation [37,39]. This indicates that the presence of NGAL in the urine in sepsis patients cannot automatically be considered as a marker of tubular damage per se. In addition, some patients with transient AKI might have some degree of tubular damage, which might explain the relatively low value of NGAL to discriminate transient from intrinsic AKI in this cohort of sepsis patients.

A strength of this study is that it describes one of the largest cohorts of sepsis patients in detail for different patho-physiologic aspects of AKI, such as urinary and serum biomarkers, and urinary output. A limitation on the other hand is that it is observational and hence no causal assumptions can be made.

Conclusion
Urinary output is an early and sensitive marker of AKI, which might incite intervention before tubular damage has occurred. Low fractional excretion of sodium (<1%) and urea (<35%) is very frequent in sepsis patients, and it might be necessary to define lower discriminatory cut-off values as an indication of maximal tubular reabsorption and thus intact tubular function as the ones used at present. A combination of high fractional excretion of sodium and urea has a high negative predictive value for intrinsic AKI, whereas a high fractional sodium excretion and a low fractional urea excretion are associated with intrinsic AKI in 54% of cases.

Key messages
- A low FENa and FEUrea are highly prevalent in the first hours of sepsis.
- Neither FENa, FEUrea, nor NGAL alone has sufficient power to discriminate intrinsic from transient AKI.
- The combination of a high FENa and a low FEUrea is associated with intrinsic AKI, whereas a high FENa and a high FEUrea are predictive of transient AKI.
- Omitting the urinary output criterion leads to underdiagnosis of AKI.
- Oliguria is an earlier sign of impending AKI than increase in serum creatinine.
