Abstract

**Background** Malaria, blood-borne filarial worms and intestinal parasites are all endemic in Gabon. This geographical co-distribution leads to polyparasitism and, consequently, the possibility of immune-mediated interactions between different parasite species. Intestinal protozoa and helminths could modulate anti-malarial immunity, for example, thereby potentially increasing susceptibility to malaria.

**Methods** Blood and stool samples were collected during cross-sectional surveys in five provinces of Gabon. Parasitological diagnosis was performed to detect plasmodial parasites, *Loa loa* and *Mansonella perstans*, intestinal helminths (STH) and protozoan parasites. Nested PCR was used to detect submicroscopic plasmodial infection in individuals with negative blood smears. Cytometric Bead Array was used to quantify interleukin (IL)-6, IL-10 and Tumor Necrosis Factor (TNF)-α in plasma of subjects with different parasitological profiles i.e. malaria only, filariasis only, intestinal protozoan only, soil-transmitted helminths (STH) only, malaria/filariasis, malaria/STH, malaria/intestinal protozoa co-infections and in uninfected individuals/control group.

**Results** Median IL-6 (124.5 [36.9–433.9] pg/mL) and IL-10 (224.5 [78.0–657.9] pg/mL) levels and the median IL-10/TNF-α (69.9 [12.5–140-7]) ratio were all significantly higher among individuals with *Plasmodium falciparum* infection compared to other groups (*p* < 0.0001). The median TNF-α level (6.5 [3.5–11.7] pg/mL) and IL-10/IL-6 ratio (3.6 [2.0–11.9]) were higher in subjects with STH (*p* = 0.09) and *P. falciparum*-intestinal protozoa co-infection (*p* = 0.04), respectively. IL-6 (rho=-0.37; *p* < 0.01) and IL-10 (rho=-0.37; *p* < 0.01) levels, and the IL-10/TNF-α ratio (rho=-0.36; *p* < 0.01) correlated negatively with age, independently of infectious status. Among children under five years old, the IL-10/TNF-α and IL-10/IL-6 ratios were higher in those with intestinal protozoan infections compared to uninfected children. The IL-10/TNF-α ratio was also higher in children aged 5-15 years and in adults harbouring blood-borne filariae compared to their control counterparts, whereas the IL-10/IL-6 ratio was lower in those aged 5-15 years with filariae and intestinal parasites but higher in adults with intestinal parasitic infections.

**Conclusions** Asymptomatic malaria is associated with a strong polarization towards a regulatory
immune response, reflected by high circulating levels of IL-10. Co-infections with *P. falciparum* and intestinal protozoa are associated with an enhanced IL-10 response. Immunity against malaria could differ according to age and carriage of other parasites.

**Introduction**

In Gabon, malaria and intestinal parasite infections (IPIs) as well as filariasis are frequently diagnosed in the population, with the prevalence varying from 1–75% [1, 2]. This geographical co-distribution can lead to polyparasitism with possible interactions between parasite species. Studies on the association between *Plasmodium* and helminths have shown that helminths could have either a protective, a detrimental or a neutral effect on plasmodial infections. For example in Mali, *Schistosoma (S.) haematobium* delayed the appearance of clinical malaria in children, while in Gabon and in Senegal it was reported that *Ascaris lumbricoides* and *S. haematobium* increased the risk of clinical episodes [3–5]. Shapiro and colleagues found no interactions between these STH and malaria parasites [6]. Although the epidemiological patterns and/or the clinical consequences of polyparasitism are being increasingly studied, data concerning the immune responses and the susceptibility to other diseases of individuals exposed to or infected by different helminth or protozoal parasites in endemic areas remain scarce. Relevant information for Gabon does not exist.

Understanding the immune response elicited by each pathogen in the case of co-infection could help with the management or the prevention of the deleterious effects of polyparasitism.

Levels of pro- and anti-inflammatory cytokines that are influenced either by the environment or by other parasites can reflect *P. falciparum* induced immunity and morbidity of populations living in regions with different malaria endemicity. Indeed, interleukin (IL-) 10 was shown to be a predictor of the occurrence clinical malaria in highly endemic areas of India while IL-6, IL-10 and IL-12 were associated with disease outcome in a non-endemic region [7]. With respect to *Plasmodium*-helminth co-infections, helminths orient the immune response toward an anti-inflammatory pathway whilst plasmodial infection is known to elicit a strong pro-inflammatory response (Boeuf et al., 2013; Hartgers et al., 2009); filaria-helminth co-infection is associated with a low IL-10 level whereas that of IL-6 was described to be lower in the case of *Plasmodium*-hookworm co-infection [10].
On the other hand, chronic intestinal helminthic and/or filarial infection are associated with high levels of IL-10 (Maizels et al. 2004). IL-10 downregulates the functions of immune cells that release pro-inflammatory cytokines, both preventing the elimination of worms and protecting the host against helminth infection-related symptoms. IL-6 is also described in the literature to increase significantly among populations infected with helminths [12]. However, the level of TNF-α is reported not to vary [12].

In a rural setting, anti-malarial immunity can be modulated by infection with *Trichurus trichiura* [13], but in urban and suburban areas data on such interactions are lacking. The heterogeneity of *Plasmodium spp.* prevalence can be due to different susceptibility patterns to *P. falciparum* infection according to the presence and type of other parasitoses. In Ghana it was shown that the production of inflammatory cytokines was inversely proportional to the level of malaria transmission [14]. The study presented here was conducted in areas of Gabon not yet investigated that have different levels of malaria endemicity. In another hand, in Gabon, intestinal protozoan were found more frequently in co-infection with *P. falciparum* comparatively to STHs [15, 16]. But it is not described if these protozoan, pathogenic or not, interact with *P. falciparum*-related immunity. Indeed, non-pathogenic protozoan carriage does not constitute a public health problem. But experimental studies on *Blastocystis* spp., a controversial pathogenic intestinal protozoa, *Entamoeba (E.) histolytica* and *Giardia (G.) intestinalis*, have demonstrated that these parasite carriage is associated with the production of pro-inflammatory cytokines [17, 18]. In humans, this immunomodulation was equally observed [19]. A study showed that *Blastocystis* spp. could downregulate immune response to another antigen as helminths [18]. So this survey evaluated the impact of intestinal parasites (helminths or protozoa) and blood filaria on the secretion of cytokines involved in malaria immunity during coinfection with helminths and protozoa.

Patients And Methods
Study sites and populations
This study was nested in cross-sectional surveys on asymptomatic malaria carried out from September 2013 to June 2016 in five out the nine provinces of Gabon with different degrees of
urbanization (Fig. 1). Samples taken from individuals participating in villages located around the main towns of the Ogooué-Ivindo and Haut-Ogooué provinces, and those from patients at the Centre Hospitalier Régional (CHR) d’Oyem, (Woleu-Ntem province), the CHR de Koula-Moutou and Dienga (Ogooué-lolo province), the CHR de Melen and the Lalala Public Health Center (Estuaire province) were used for this study. Lalala is a suburban area of the capital city of Libreville, an urban area; the CHR of Melen is located in a suburban area and the CHR d’Oyem, of Koula-Moutou as well as villages in the Ogooué-Ivindo and Haut-Ogooué and Dienga are located in rural areas.

Inclusion criteria for sample selection included for the study participants: absence of fever (axillary temperature ≤ 37.5 °C) or absence of history of fever the day of the screening and during the week preceding the consultation, absence of other clinical symptoms suggestive of malaria, absence of antimalarial drug uptake the last two weeks, absence of any other severe medical condition and sickle cell disease, permanent residence in the study area, agreement to fill the questionnaire and written informed consent.

All the plasma controls were those from individuals with no history of or current *P. falciparum* or intestinal parasite infection.

**Procedures For Sample Selection For This Immunological Substudy**

During the main surveys, patient recruitment, demographic, socioeconomic, environmental and parasitological data were collected in standardized case report forms. Among the 843 patients recruited for the main surveys, 400 provided blood and stool samples. After the microscopic diagnosis of blood and intestinal parasites, blood samples of those with negative blood smears were screened for submicroscopic plasmodial infection by nested polymerase chain reaction after DNA extraction using QIAamp® kit.

Then, five groups of samples from participants with different profiles of parasitic infection were constituted: plasma from those with (i) *Plasmodium spp.* infection alone, (ii) helminth infection (blood-borne filariae and intestinal worms), (iii) intestinal protozoan infection alone, (iv) *Plasmodium spp./helminth* co-infection and (v) *Plasmodium spp./intestinal protozoan* co-infection. The latter group included samples without detected parasites according to the method used for diagnosis; individuals
with no parasites constituted the control group.

Ethical Consideration
This nested study received ethical clearance from “Comité National d’Ethique pour la Recherche” (CNER) of Gabon. The protocol and the questionnaire were also approved by the Ministry of Health.

Sample Processing
After collection, whole blood was used for microscopic malaria and blood filarial diagnosis. After centrifugation blood pellets were stored at −20 °C for the molecular detection of *P. falciparum*; plasmas were directly stored at -20 °C on site, then transported to the laboratory in a cooled container and stored at −80 °C prior to immunological analysis. The participants were provided with clean, labelled stool collection pots with clear instructions to ensure that stool samples were collected correctly.

Parasites Microscopic Diagnosis
The detection of plasmodial parasites was performed by thin and thick smears using the Lambaréné method [20]. Whole blood direct microscopic examination and leukoconcentration techniques allowed for the identification of blood filariae *L. loa* and *M. perstans* [21]. To determine the presence of intestinal parasites, three techniques were performed: direct stool examination, Merthiolate-Iodine-Formaldehyde coloration and parasite culture. These techniques are described in detail elsewhere [15].

DNA Extraction And Submicroscopic Plasmodial Infection
DNA was extracted from peripheral blood collected in EDTA tubes using the QIAamp® kit (QIAGEN®) according to the manufacturer’s instructions. The 18S rRNA malarial genes were amplified by nested PCR according to the protocol described by Snounou and Singh [22]. Briefly, for the first reaction, rPLU 1 (5’ TCA AAG ATT AAG CCA TGC AAG TGA 3’) and 5 (5’ CCT GTT GTT GCC TTA AAC TCC 3’) primers pairs were used. The product generated in this reaction served as a template in the second reaction, performed with an rPLU 3 (5’ TTT TTA TAA GGA TAA CTA CGG AAA AGC TGT 3’) and 4 (5’ TAC CCG TCA TAG CCA TGT TAG GCC AAT ACC 3’) primers pairs allowing the generation of a 235 bp fragment. The visualization of the PCR products was carried out using 2% agarose gel electrophoresis. Participants identified as *Plasmodium sp.* infected had positive PCR results or positive thick smears.

Circulating Cytokines Measurement
A Cytometric Bead Array human cytokine kit from Becton Dickinson (CBA kit, BD Biosciences, San Diego, CA, USA) was used to measure plasma levels of IL-6, IL-10 and TNF-α according to the manufacturer’s instructions. Samples were centrifuged and one volume of the supernatant obtained was diluted into two of the assay diluent. Then, the technique was realized as described by Böstrom and colleagues [23]. The highest standard concentration was 2500 pg/mL and the lowest was 5 pg/mL. The calibration, the sample acquisition and the standard was performed using a BD FACSCalibur flow cytometer (FACSCalibur, Becton Dickinson, Le pont de Claix Cedex, France), and results were analysed with FCAPArray v1.0.1 software (SoftFlow, Pécs, Hungary). The detection limits of cytokines were 1.6 pg/mL, 0.13 pg/mL and 1.2 pg/mL for, respectively, IL-6, IL-10 and TNF-α. If the cytokine concentration was below the detection limit, a value corresponding to half the detection limit was assigned to the sample.

Statistical analysis
Statview Version 5.0 (SAS Institute Inc.) was used for statistical analysis and GraphPad Prism Version 5.03 and Statview Version 5.0 (SAS Institute Inc.) for graphical representations of box plot and scatter column. Cytokine concentrations were transformed to log_{10} function for graphical representation. IL-10/TNF-α and IL-10/IL-6 ratios were calculated for each sample. The ranges of cytokine concentrations, *Plasmodium sp.*, *L. loa* and *M. perstans* parasitaemia and eosinophilia did not follow normal distributions and descriptive analyses of these quantitative variables are presented with medians [interquartile ranges, IQR: 25th – 75th quartiles]. Tests for comparison of cytokines and ratios were performed firstly using the Kruskal–Wallis test for a global comparison, then the Mann–Whitney U test for a comparison of medians of two groups with different infection profiles. In order to perform multivariate analysis, R software was used to build and evaluate some models. F-tests were performed to statistically test the equality of means into different groups, according to age, location, parasitaemia. A p-value less than 0.05 was considered significant.

Results
Samples of 240 participants were selected for the immunological analysis (Fig. 2). Out of the 208 patients for whom the area was known, 172 (82.7%) were from a rural area (Table 1). Age was
recorded for 224 of them and the median age was 22.5 [6.0–48.8] years old. Adults represented more than half of the study population (58.0%; 130/224) and children less than 5 years old, 21.0% (47/224). The sex ratio was 0.8 and did not differ according to age and site.

Table 1

Distribution of the groups with different parasitic profile according to sex, age and location

|                | Total (n=224) | No parasites (n=35) | P. falciparum only (n=50) | Filariasis (n=48) | STH (n=43) | Intestinal protozoa only (n=39) | Plasmodium/filariae co-infection (n=7) | Plasmodium/STH co-infection (n=7) | Plasmodium/intestinal protozoa co-infection (n=17) |

p-values were obtained using the Fisher’s exact test.

Microscopic and molecular diagnoses combined showed the prevalence of *Plasmodium* infection alone to be 20.8% (50/240). *P. falciparum* was the only species identified. Intestinal helminths (STH) and filariasis infections were detected in 43 (17.9%) and 48 (20.0%) individuals respectively, and intestinal protozoan monoinfection in 39 (16.3%). *A. lumbricoides* (14.6%; 35/240), *T. trichiura* (13.7%; 33/240), *Blastocystis* spp (36.2%; 87/240), *E. histolytica/dispar* (7.1%; 17/240) were the most frequently detected intestinal parasites; *G. duodenalis* and *S. stercoralis* were each one found in 5/240 (2.1%) samples only. *Schistosoma* species were not detected in any of the samples. The rates of *P. falciparum*/STH and *P. falciparum*/filariae co-infections were 2.9% (7/240) and that of *P. falciparum*/intestinal protozoa co-infection, 7.1% (17/240).

Prevalence of parasitic infection of any type was highest in adults (87.7%; 114/130), followed by those aged 5 to 15 years old (87.2%; 41/47) and lowest in children less than 5 years old (72.3%; 34/47) (p < 0.01). Adults were more frequently infected than children (Table 1). The prevalence of filariae (97.7%), STH (70.5%) and intestinal protozoa (48.7%) was significantly higher among adults
compared to children (p < 0.01, Table 1). Moreover all those co-infected with *P. falciparum*/filariae were adults. The proportions of individuals with *P. falciparum*/STH co-infections and *P. falciparum*/intestinal protozoan co-infections were greatest respectively in younger children (50.0%) and those aged between 5 and 15 years old (52.9%).

The median *P. falciparum* parasitaemia was significantly higher in cases of monoinfection (9450 [1296–36400] T/µL (p ≤ 0.04) while it was lower in those with either STH (42 [12.3-681.5] T/µL), filarial (350 [16-1400] T/µL) or intestinal protozoan (749 [35-10150] T/µL) co-infections (p ≤ 0.04). *L. loa* and *M. perstans* parasite densities were comparable between groups. Intestinal protozoa were found to be more frequently associated with other parasites (28.7%; 69/240).

**Cytokine Levels In Uninfected Individuals**

IL-6, IL-10 and TNF-α median levels were 14.2 [4.7–68.0] pg/mL, 11.1 [8.0-15.2] pg/mL and 5.4 [4.6-6.8] pg/mL respectively. The IL-10/TNF-α ratio was 2.0 [1.4–3.2] and that of IL-10/IL-6, 1.2 [0.2–2.3]. The “No parasite” group was used as reference to estimate an increasing, a decreasing and comparable cytokine levels and cytokine ratios.

**Cytokine Levels In Parasitized Individuals**

IL-6 median levels were higher among those with single *P. falciparum* (124.5 [36.9-433.9] pg/mL) and a *P. falciparum*/STH co-infection (25.5 [4.4–60.8] pg/mL) (p < 0.01). IL-10 was also higher in participants with *P. falciparum* single infection (224.5 [78.0-657.9] pg/mL) and in co-infected *P. falciparum*–filariae (18.1 [12.8-125.2] pg/mL), STH (39.5 [33.0-68.0] pg/mL) and intestinal protozoa infected ones (26.9 [8.7–60.1] pg/mL) (p < 0.01). STH-infected individuals had a higher median TNF-α level compared to the uninfected. The IL-10/TNF-α ratio was on average 30-fold (69.9 [12.5-140.7]), 10-fold (19.7 [1.6-115.2]), 6-fold (13.0 [3.5–24.9]) and 8-fold (16.9 [2.4–86.6]) higher in those with single or *P. falciparum* co-infections with filariae, STH and intestinal protozoa respectively, compared to uninfected participants (p < 0.0001). The IL-10/IL-6 ratio tended to be higher in those with *P. falciparum* infections alone (2.0 [0.9–3.6]), it was 2-fold (2.5 [1.8–4.7]) and 3-fold (3.6 [2.0-11.9]) higher in those with dual infections with malaria/filariae and malaria/intestinal protozoans, respectively.
Figure 4a and 4b show pairwise comparisons of cytokine median concentrations and ratios. TNF-α levels did not differ significantly according to the presence or the type of parasitic infection (Fig. 4), except in the case of STH single infection (6.5 [3.2–11.7] pg/mL). Those with STH (8.0 [4.7–12.7] pg/mL), intestinal protozoa (8.9 [6.8–14.5] pg/mL), filariae (6.9 [3.3–13.4] pg/mL) mono-infections had lower median IL-10 levels than those with, respectively, a P. falciparum/STH co-infection (39.5 [33.0–68.0] pg/mL), a P. falciparum/intestinal protozoa co-infection (26.9 [8.7–60.1] pg/mL) and a P. falciparum/filariae co-infection (18.1 [12.8–125.2] pg/mL). STH infected-individuals had lower IL-6 concentrations than P. falciparum/STH co-infected ones. Cytokine level was also lower in those with intestinal parasitism and filariasis (Table 3). Intestinal protozoan infected-subjects had a higher IL-10/IL-6 ratio compared to uninfected individuals ($p = 0.04$).

| Cytokines       | Median level of pro- and anti-inflammatory cytokines according to parasitic profile |
|-----------------|-------------------------------------------------------------------------------------|
|                 | Global | No parasites | Malaria only | STH | Filariasis | Intestinal protozan only | Malaria/filaria co-infection | Malaria/STH co-infection | Malaria/intestinal protozan co-infection | p        |

**Multivariate Analysis**

Comparison of the IL-6, IL-10 and TNF-alpha levels, and of the IL-10/IL-6 and IL-10/TNF-alpha ratios in the 8 different parasitic groups adjusting by age, urbanization and *P. falciparum* parasitaemia showed no statistically significant differences (p > 0.05). Cytokine concentrations and cytokine ratios were similar across the age groups after adjusting for parasitic infections and urbanization.

**Discussion**

This study is the first to analyse the influence of single or multiple parasitic infections on the plasma cytokine profile of Gabonese individuals. The main aim was to determine the relationship between intestinal parasitoses, as well as loiasis, and the plasma concentrations of different cytokines implicated in malaria pathophysiology.

Lower parasitaemias were observed among participants carrying co-infections of either *P. falciparum*-intestinal parasites or *P. falciparum*-filariasis compared to those with only *P. falciparum*, suggesting an effect of intestinal parasites and filariae on *P. falciparum* multiplication. Lower parasite burdens, in the presence of intestinal helminth infections, have been reported elsewhere [24, 25]. According to these authors, one explanation could be the existence of immune cross-reactivity between intestinal parasites and *Plasmodium sp*. Indeed, both parasites induce Th2 immune response and specific IgG3
produced as a result of intestinal parasitic infection could neutralize plasmodial parasites [26]. In the case of protozoan co-infections, no impact of intestinal protozoa on Plasmodium sp parasitaemia has been described.

*P. falciparum*-infected participants, who were asymptomatic when included, had higher median levels of IL-6 and IL-10 compared to the control group, but no difference in the level of TNF-α level. In the context of IL-10, this result is consistent with the findings of earlier studies [27, 28]. The immune-regulatory and anti-inflammatory cytokine IL-10 is known to downregulate Th1-type cytokines such as IL-6, TNF, and IL-1 [29]. Here, we found IL-10 to be implicated in the inhibition of the production of the TNF-α but not of IL-6 during plasmodial infection. It is possible that the downregulation of TNF is correlated with the absence of clinical signs. TNF-α did not vary in the control group compared to *Plasmodium*-infected participants with. TNF-α is the cytokine most implicated in the development of the clinical signs of malaria [30], whilst IL-10 and IL-6 are present at high levels in patients with symptomatic malaria [31-33]. The asymptomatic status of participants at the time of the study presented here could indicate the acquisition of premunition which limits the appearance of clinical symptoms, and/or that participants were sampled at an early stage of the infection, before progression toward symptomatic disease [34]. It is important to note that, in the current Gabonese context, younger children are found to be less frequently infected by malaria parasites than older children [15, 35] and the number of adults presenting with clinical malaria is increasing, suggesting a loss of malaria premunition. This epidemiological picture most likely primarily reflects the switch, since 2003, to the use of artemisinin combination therapy for malaria in under-five year old children.

Previous studies conducted in Gabon showed malaria to be co-endemic with other parasitic infections that are present at a similar or higher prevalence (compared to malaria) and that can alter immunity to malaria (Akue et al., 2011; Bouyou-Akotet et al., 2015; M’Bondoukwé et al., 2016, 2018). Here, intestinal parasite infection (IPIs) and blood filariasis were associated with decreased Th1 (IL-6) and Treg (IL-10) responses. *Blastocystis sp.*, the most prevalent intestinal parasite, have immunomodulatory effects with induction of pro-inflammatory cytokine responses [38]. The prevalence of *Blastocystis* has increased across the country [15, 16]. Therefore, it was hypothesized
that, together with its implication in dysbiosis, *Blastocystis* could affect cytokine production and influence *P. falciparum* carriage. A study in Pakistan showed that *Blastocystis sp.* type 1 was associated with low IL-10 production in the blood, but that in stool samples *Blastocystis sp.* generates an anti-inflammatory environment [19, 39].

The impact of other pathogenic intestinal protozoa on the cytokine profile was not investigated here because of the low number of infected patients and the absence of single *E. histolytica* and *G. duodenalis* mono-infection or co-infection with *P. falciparum*. However, during intestinal protozoa/*P. falciparum* infection, a significant reduction of pro-inflammatory cytokines (IL-6, TNF-α) was observed, suggesting that infection with *G. duodenalis*, *E. histolytica*, or *Blastocystis sp.* decreases the *P. falciparum*-induced Th1 response, thereby contributing to the absence of clinical symptoms. This would also explain the difference in IL-10 levels between participants with intestinal protozoa and those from the control group. The implication of each of these three protozoan parasites as well as the different subtypes of *Blastocystis sp.* on the global and specific cytokine response merits further exploration.

Individuals with a low Th2-Treg/Th1 ratio are less susceptible to malaria but have a greater likelihood of clinical disease when infected [40, 41]. Here we observed that IL-10 and IL-6 levels were 1.3 to 18.0-fold lower in those with malaria-intestinal parasite co-infections (both helminths and protozoa) (data not shown) compared to those with plasmodial mono-infections, although still higher compared to uninfected participants. A trend towards a down regulation of TNF-α was observed in co-infections with intestinal parasites. This regulatory effect on pro-inflammatory cytokine production during helminth and *P. falciparum* co-infections is well-described (Bustinduy et al., 2015, Sinha et al., 2010). Elevated IL-10 levels have been observed in patients with *Plasmodium*-schistosomiasis and malaria-hookworm co-infection (Bustinduy et al., 2015, Courtin et al., 2011, Diallo et al., 2004; al., 2003). The higher IL-10/TNF-α ratio, in the group of participants with *Plasmodium* mono-infection compared to *Plasmodium/helminth* co-infection suggests a lower risk of developing clinical signs in case of STH/*P. falciparum* co-infection as demonstrated by Frosch & John (2013). Additionally, the IL-10/IL-6 ratios suggest that with *Plasmodium* and intestinal protozoa co-infected participants seem also to be less at
risk to have symptoms. Thus, exposure to both IPI and malaria via the increasing prevalence of intestinal parasites in the country would partly explain the increasing frequency of asymptomatic *P. falciparum* carriage observed in the country [35, 42, 43]. But a meta-analysis of young African children with helminth-*P. falciparum* co-infections concluded that they are more susceptible to *P. falciparum* infection [44]

IL-10/TNF-α ratios show that filariae-infected volunteers more than 5 years old have a higher risk of *P. falciparum* infection than participants infected with other parasites. But when the IL-10/TNF-α (except for STH infection) and IL-10/IL-6 ratios were analyzed, children with intestinal parasites were found to be more susceptible to *P. falciparum* infection presenting higher values. Intestinal helminths and filarial infections are associated with higher production of IL-10 and consequently with the inhibition of Th1-type cytokine production [12, 45, 46]. The high IL-10/TNF-α and IL-10/IL-6 ratios observed here in those with helminth co-infections are consistent with such observations.

The development of the anti-infectious immune response is promoted by repeated exposures and the chronicity or persistence of infections. The immune response was studied according to age in uninfected, mono-infected or polyparasitized participants. It differed according to age and type of parasitism. The negative correlation between cytokine levels and age is in favor with a greater stimulation in young children. They are actually more at risk of the studied parasites (with the exception of filariasis) and polyparasitism [15]. Although, the cross-sectional design of this study, does not allow to confirm that the measured cytokine levels were baseline. Nevertheless, the fact that participants lived in the study area since several months without significant interventions related to malaria or IPI, allow a comparison between the different groups determined according to the presence and the type of infection. The low level of IL-10 among children with STH, may be due simply to the reduce time of exposition to induce a typical T-regulatory-related IL-10-dominated response as they are younger, as observed in Kenyan children [10]. The decrease in the IL-6 level in case of intestinal protozoan can be related to an immunoregulatory effect induced by these parasitosis; this is confirmed by the high IL-10/TNF-α ratio. The analysis of the IL-10/IL-6 ratio which shows a different profile than that of each cytokine would highlight the predominance of the anti-inflammatory cytokine
response in young children infected with STH and intestinal protozoa. In contrast, in adults, the comparable level between infected and uninfected ones, is probably linked to a better control of these infections through a protective and mature immune response.

The predominance of a pro-inflammatory cytokine profile in the absence of infection may be linked to the greater susceptibility of young children to severe malaria which is determined by high IL-6 and TNF response. This could partly explain the predominance of severe forms of malaria in young children, although they remain less frequently infected \[35, 47\]. Indeed, the lower basal cytokine Th1 level in healthy children could indicate their greater susceptibility to plasmodial infection due to a less efficient control of *Plasmodium* multiplication that would quickly reach the pyrogenic threshold. In contrast, the downregulation of IL-10 observed in older children would be in favour of a less control of the parasite multiplication at the beginning of infection and therefore of a higher frequency of parasitaemia in this group compared to the young people.

**Limits**

The cross-sectional design is one of the main limits of this study. Also, plasma cytokines cannot be considered as being specifically induced by any given parasitic infection. Specific and more sensitive techniques such as stimulation of PBMC *in vitro* to assess responses to *P. falciparum*, intestinal parasites and filariae would be useful in this context. Equally, next generation sequencing would give a global picture of the immune response by measuring the transcript levels of Th1-, Th2- and Treg-related cytokines. The influence of helminths and intestinal protozoa on innate and adaptive responses to *P. falciparum* could thus be revealed. The small sample size in groups with different parasitic infections could also explain the lack of association between the cytokine levels and infection profiles in multivariate analysis. However, the present results already give a baseline estimation of the overall *in vivo* cytokine levels implicated in anti-parasite immunity in exposed individuals according to their age.

**Conclusion**

This study demonstrates the implications of blood filariae, intestinal parasites (helminths and protozoa) on the cytokine responses involved in susceptibility to infection with *P. falciparum*. STH seem to have a protective effect on malaria according to the IL-10/TNF-α ratio, while with the IL-10/IL-
6, intestinal protozoa may have a detrimental effect. These parasites which are co-endemic with
*Plasmodium falciparum* in Gabon also seem to alter the susceptibility to *P. falciparum* infection
according to age. Those more than 5 years old and adults seem to be more at risk of infection when
co-infected with filariasis associated with a higher IL-10/TNF-α ratio, and when co-infected with
intestinal parasites associated with a higher IL-10/IL-6 ratio. The low number of cases of helminth/*P.
falciparum* co-infections could have affected interpretation of our results, however.

**Declarations**

Ethics approval and consent to participate
This nested study received ethical clearance from “Comité National d’Ethique pour la Recherche”
(CNER) of Gabon. Participants were informed before to enrolled in the study and accepted that
plasma will used for immunological studies. The protocol and the questionnaire were also approved
by the Ministry of Health.

Consent for publication
Not applicable

Availability of data and materials
The datasets used and/or analysed during the current study are available from the corresponding
author on reasonable request.

Competing interests
The authors declare that they have no competing interests.

Funding
This study was funded by the Department of Parasitology-Mycology of Tropical Medicine, RELACS
network and the Gabonese Red Cross for the data and sample collection on the field. CECAGADIS, a private corporate from Gabon, funded this project, for immunological analysis carried out in Benin.

Authors' contributions
MKB-A was the principal investigator and conceived the study with NPM. NPM carried out plasma aliquots and performed Cytometric Bead Array with KA, RA and TH in Benin. AFJL brought the technical platform and supervised the immunological analysis. MKB-A and NPM wrote the paper. DPM-M, JMNN and JMNN reviewed and edited the paper. The statistical analyses were carried out by MKB-A, MNP and KP and MKB-A, MNP proceeded to the interpretation of the data.

Acknowledgements
We would like to thank the members of the Red Cross in Libreville and the Ministry of Health for giving permission and logistical support for this study to be conducted. We are also grateful to the study participants.

Figures
Figure 1

Study sites where samples were collected. Red circles represent many villages around the site and red full stop, one site.
Figure 2

represents a flow chart ranging to the enrolled population, followed by prevalence of parasites found in the study population to different groups with different parasite profile.
Figure 3

Cytokines profiles stratified by areas according to age in months. IL-10 level decreased when age increased in rural area. IL-10/TNF-alpha ratio increased with age in rural area but decreased in urban area.
Figure 4:
Box plot displaying IL-6, TNF-α and IL-10 cytokine production and IL-10/TNF-α, IL-10/IL-6 median ratios according to different parasitic profile. Mann-Whitney test was carried to pairwise comparisons. Values used for the graphical representation were log-transformed.

Figure 4b: represents comparisons in rural area.
