Somatic mutations in single human cardiomyocytes reveal age-associated DNA damage and widespread oxidative genotoxicity

Sangita Choudhury, August Yue Huang, Junho Kim, Zinan Zhou, Katherine Morillo, Eduardo A. Maury, Jessica W. Tsai, Michael B. Miller, Michael A. Lodato, Sarah Araten, Nazia Hilal, Eunjung Alice Lee, Ming Hui Chen, and Christopher A. Walsh

The accumulation of somatic DNA mutations over time is a hallmark of aging in many dividing and nondividing cells but has not been studied in postmitotic human cardiomyocytes. Using single-cell whole-genome sequencing, we identified and characterized the landscape of somatic single-nucleotide variants (sSNVs) in 56 single cardiomyocytes from 12 individuals (aged from 0.4 to 82 years). Cardiomyocyte sSNVs accumulate with age at rates that are faster than in many dividing cell types and non-dividing neurons. Cardiomyocyte sSNVs show distinctive mutational signatures that implicate failed nucleotide excision repair and base excision repair of oxidative DNA damage, and defective mismatch repair. Since age-accumulated sSNVs create many damaging mutations that disrupt gene functions, polyploidization in cardiomyocytes may provide a mechanism of genetic compensation to minimize the complete knockout of essential genes during aging. Age-related accumulation of cardiac mutations provides a paradigm to understand the influence of aging on cardiac dysfunction.

Results
Cardiomyocyte polyploidization starts early in life. To identify and isolate cardiomyocyte nuclei from heart tissue, we purified cardiac nuclei from fresh-frozen, unfixed, left ventricle human myocardium by density sedimentation (Supplementary Table 1)6. Cardiac nuclei were identified with cardiac troponin T (cTropinin T) staining (Fig. 1a,b,d and Extended Data Fig. 1a), which is a well-characterized cardiomyocyte-specific marker6,15. Although the pericentriolar material 1 (PCM1) antibody is used widely to identify cardiomyocyte nuclei, it has been shown that about 20% of PCM1-positive nuclei correspond to nonmyocyte cells16. Careful doublet exclusion was performed by plotting the area for forward scatter (FSC) and side scatter (SSC) against the height (H) or width (W); H versus W or area (A) allows the separation of doublets
Somatic mutations increase with age in cardiomyocytes. We evaluated the genome-wide burden of sSNVs using single-cell whole-genome sequencing (WGS) of DNA amplified from 48 tetraploid and 8 diploid single-cardiomyocyte nuclei from postmortem hearts of three infants (<4 years), six middle-aged (30–66 years) and three aged individuals (>75 years) (Fig. 2a and Table 1). Cardiomyocyte nuclei were isolated from the left ventricle, and DNA was amplified using multiple displacement amplification (MDA) followed by quality control steps (Methods) and then high-coverage (>50x) WGS on selected, well-amplified cells (Supplementary Table 2). We identified single-cell sSNVs from each cardiomyocyte (Supplementary Table 3) using a modified version of the LiRA algorithm, which uses read phasing information from adjacent germline variants to distinguish true somatic mutations from technical artifacts arising during whole-genome amplification and sequencing. The LiRA algorithm has been demonstrated to effectively remove most false positives. We also estimated the genome-wide sSNV burden for each cardiomyocyte (Supplementary Table 4), after taking cell-specific dropout rates and sequencing depth distributions into consideration to account for the tetraploid effect on detection sensitivity and power calculation, and subtracting the contribution of potential artifacts due to MDA amplification based on their highly distinctive nucleotide substitution pattern (Methods). We also measured the MDA amplification evenness across the genome for each single-cell using median absolute pairwise difference (MAPD) and coefficient of variation (CoV) of binned normalized copy number ratios, and incorporated them as covariates in our subsequent regression analyses.

Tetraploid cardiomyocytes showed a significant increase of sSNV with age ($P=7.3 \times 10^{-4}$, mixed-effects regression; Fig. 2b) at a rate of 0.010 sSNV Mb$^{-1}$ year$^{-1}$ (or 124 sSNV cell$^{-1}$ year$^{-1}$), and the sSNVs were distributed broadly across the genome (Fig. 2c). Note that, in each age group, there are notable intraindividual and interindividual variations, particularly in the aged group, where a few outlier nuclei showed a very high sSNV burden (>2 sSNV Mb$^{-1}$). We further confirmed the age-dependent increase in diploid cardiomyocytes, in which the aged heart showed significantly more sSNVs than the infant heart ($P=0.014$, two-tailed t-test; Fig. 2d). We observed nearly doubled per-genome sSNV rate in tetraploid cardiomyocytes when compared with diploid cardiomyocytes, but, after normalizing to their different genomic size, no significant difference was observed between tetraploid and diploid cardiomyocytes obtained from infant and aged donors ($P=0.11$ and 0.86, two-tailed Wilcoxon test; Extended Data Fig. 2a), suggesting a consistent increase of sSNV in human heart muscle cells with age, regardless of cardiomyocyte nuclear ploidy. Since two of our donors were affected by ventricular hypertrophy (cases 5657 and 5840), we remeasured the age-associated increase after excluding cardiomyocytes obtained from these two donors, and still observed a consistent increase rate (0.010 sSNV Mb$^{-1}$ year$^{-1}$; $P=6.1 \times 10^{-4}$, mixed-effects regression).

To better understand the age-dependent sSNV accumulation in cardiomyocytes, we first compared the accumulation rates between cardiomyocytes and neurons, another nondoning human cell type. We found that cardiomyocytes accumulate sSNVs around three times faster than neurons (0.003 sSNV Mb$^{-1}$ year$^{-1}$ or 19 sSNV cell genome$^{-1}$ year$^{-1}$; $P=2.1 \times 10^{-3}$) between cardiomyocyte and neuron, mixed-effects regression; Fig. 2e), suggesting that cardiomyocytes and neurons might undergo different mutational processes during aging. The age-dependent increase in cardiomyocytes and the cardiomyocyte-neuron difference remained significant ($P<0.05$) even after controlling potential confounding factors including MAPD and CoV scores (measurement of amplification evenness), sequencing depth, library insert size, number of heterozygous germline SNVs and postmortem interval (PMI), as well as excluding C3-T sSNVs (Extended Data Fig. 3; Methods). We further compared the sSNV accumulation rate in cardiomyocytes with hepatocytes—the liver cells of another highly active metabolic organ—and mitotically active lymphocyte blood cells profiled by other groups (Fig. 2e). We found that cardiomyocytes accumulated sSNV at a rate similar to that of hepatocytes (0.009 sSNV Mb$^{-1}$ year$^{-1}$) considering diploid genome or 55 sSNV cell$^{-1}$ year$^{-1}$; $P=0.54$ between cardiomyocyte and hepatocyte, mixed-effects regression) but significantly higher than lymphocytes (0.004 sSNV Mb$^{-1}$ year$^{-1}$ or 22 sSNV cell$^{-1}$ year$^{-1}$; $P=2.0 \times 10^{-4}$) between cardiomyocyte and lymphocyte, mixed-effects regression).
Signature analysis identifies distinct mutational processes in aging cardiomyocytes. Different types of mutagenesis processes manifest different mutational signatures on the genome, offering insight into the molecular mechanisms involved in their formation\textsuperscript{26}. Using 10,407 sSNVs identified from 48 tetraploid cardiac nuclei (Supplementary Table 3), we first studied the base substitution distribution of age-accumulated sSNVs by subtracting the sSNV profiles of infant cardiomyocytes from those of aged cardiomyocytes, and observed that C>T and T>C mutations accumulated predominantly during the aging process (Fig. 3a). To further decipher mutational processes in the aging heart, we deconvoluted the sSNV profiles of all cardiomyocytes into mutation signatures using non-negative matrix factorization (NMF)\textsuperscript{27}. Cardiac sSNVs were best fit into four distinct mutational signatures, referred to in
this study as Signature A, B, C and D (Extended Data Fig. 4 and Extended Data Fig. 5). Signature B consisted mainly of C>A mutations, depleted at CpG dinucleotides, and matched closely with mutational signatures that were previously ascribed to artifacts created by MDA amplification29, so Signature B was removed from mutation burden analysis and not considered further. We compared our cardiac signatures with single-base substitution (SBS) signatures annotated by the COSMIC (Catalogue Of Somatic Mutations In Cancer) database30, a curated list of reference signatures generated from distinct types of human cancer, many of which had linked their mutagenesis mechanisms to various environmental factors and intrinsic processes. Further, we confirmed that tetraploid and diploid cardiomyocytes showed a similar contribution of Signatures A, C and D (Extended Data Fig. 2b,c,d).

Signature A comprised mainly C>T and T>C mutations (Fig. 3b), and its contribution in cardiomyocytes increased with age (Fig. 3c). Signature A closely resembled and was contributed dominantly by SBS5 (Fig. 3d and Extended Data Fig. 6), an age-related, 'clock-like' signature previously observed in many cancers31, normal cycling cells32 and single neurons33. This signature has been proposed to reflect faulty repair of deamination of methylated cytosines to thymine that frequently occurs in the CpG context34. thymine that frequently occurs in the CpG context29.

Signature C was distinct from the other signatures due to the prominent enrichment of C>A mutations (Fig. 3b). C>A mutations often reflect faulty repair of 8-oxoguanine (8-hydroxyguanine (8-oxo-Gua)), created by oxidative DNA damage35—one of the most common threats to genome stability36. The heart is thought to generate 8-oxo-Gua37. Decomposition of Signature C revealed significant contributions of SBS8, SBS18, SBS32 and SBS39 (Fig. 3d). SBS8 and SBS18 have been associated with the transcription-coupled repair of damaged guanine by ROS via nucleotide excision repair (NER)38 and base excision repair (BER)39 pathways, respectively, suggesting that the C>A mutations may reflect the accelerated accumulation of oxidative DNA damage that overwhelms these repair pathways.

Signature D was also enriched for C>T and T>C mutations but distinct from Signature A in its trinucleotide content (Fig. 3b). Signature D closely resembled COSMIC SBS44 (Extended Data Fig. 6) along with significant contributions from SBS6, SBS39, SBS42 and SBS46 (Fig. 3d). Both SBS6 and SBS44 have been associated with defective DNA mismatch repair (MMR) machinery and are increased in tumors associated with loss of MMR genes40. MMR is regulated by a small set of MMR-specific proteins in all cells41. Mutagenesis in the absence of one of the core MMR factors is shaped by the sequence spectrum of the unrepaired mismatches, which themselves are the product of the insertional specificity and proofreading activity of DNA polymerases. Signature D showed a striking similarity to the mutational signature of MSH6-defective human HAP1 cells, or the DLD-1 human colorectal cancer cell line, dominated by C>T and T>C mutations42 in a range of contexts, and small contributions of C>A, C>G, T>A, and T>G mutations. Signature D hence likely reflects a defect in the repair of damage that involves almost all mismatches.

Comparative signature analysis between cardiomyocytes, neurons, hepatocytes and lymphocytes shows shared and distinct mutational signatures (Fig. 3c). The age-dependent acceleration of Signature A was observed in all four cell types (P<0.001, mixed-effects regression; Fig. 3c); we did not observe a significant difference in the rate of increase between cardiomyocytes and neurons (P=0.24), which might suggest a similar 'clock-like' accumulation of such mutations among postmitotic cell types. Signature C also increased with age in all four cell types, but at a relatively similar rate...
Potential sources and mechanisms of mutation formation in the aging heart. To understand how mutations can be formed and accumulate during aging in the absence of cell cycling, it is important to recognize that both MMR, BER and NER involve steps of exonuclease removal of a segment of DNA, followed by replication of the remaining strand to reconstitute double-stranded DNA, using the undamaged strand as template. Although oxidative base lesions are commonly repaired via the BER pathway, and NER is the main pathway for the repair of bulky adducts and other helix-distorting lesions, recent evidence has suggested a role for NER proteins in the repair of oxidative damage through interactions with BER proteins\(^{38-40}\). Our analysis of mutational signatures (Fig. 3b,d) suggested a model in which oxidative stress leads to an increased overall lower gene expression for the core components of the MMR complex (MLH3, MSH2, MSH3, MSH6, PMS1 and PMS2) in heart samples compared with brain samples (\(P = 2.5 \times 10^{-6}\), two-tailed paired Wilcoxon test; Fig. 4a), and a significantly stronger decrease of those gene expression levels with aging in heart samples (\(P = 0.04\), linear regression; Fig. 4a), suggesting compromised MMR activity in aged heart, except one of the MMR complex protein MLH1. Existing evidence from primary endometrial cancer studies indicates a highly variable expression pattern of MMR complex proteins even in clinical cases and the decrease of one or more MMR complex proteins is considered damaging\(^{42}\). The age-dependent decreasing of gene expression in human cardiomyocytes was further confirmed for most MMR complex genes in a recent single-cell RNA-seq dataset\(^{41}\).

We also examined the expression of NER and BER pathway genes among GTEx heart and brain samples (Extended Data Fig. 7). We observed a twofold slower reduction of gene expression for NER and BER pathway genes in heart samples with age (\(–0.014 \text{ year}^{-1}\); \(P = 0.22\) and 0.04) than the MMR pathway (\(–0.030 \text{ year}^{-1}\)). This suggested that the MMR pathway might be affected more severely during the aging of cardiomyocytes, which could potentially explain the cardiomyocyte-specific accumulation of sSNVs from the MMR-related Signature D.

Under physiological conditions, ROS are scavenged by the antioxidant system, but when the ROS concentration is very high, oxidative damage occurs to DNA. Guanosine is the most oxidized among the DNA nucleobases, with 8-hydroxy-2-deoxyguanosine (8-OHdG) being a product of oxidative DNA damage and considered as a biomarker of oxidative stress. High levels of 8-OHdG have been correlated with various age-related cardiovascular disease progression\(^{43}\), but the exact causal relationship has not been fully elucidated. We directly assessed potential oxidative damage in the left ventricular cardiomyocytes (\(n = 10\), five infant and five aged donors) using an enzyme-linked immunosorbent assay (Methods).

We found that the level of 8-OHdG in aged hearts was more than twice as high as that in infant hearts (\(P = 0.008\), two-tailed Wilcoxon test; Fig. 4b). These data suggest that increased oxidative stress leads to elevated 8-OHdG, which may overwhelm DNA repair systems, and contributes, at least in part, to the increased DNA mutational burden.

### Table 1 | Case information analyzed in this study for sequencing

| Case ID | Age (years) | Height (inches, range) | HW (g) | BW (lb, range) | Sex | Diagnosis | Cause of death | Hypertrophy/ fibrosis? | RIN | PMI (h) |
|---------|-------------|------------------------|--------|----------------|-----|-----------|-----------------|----------------------|-----|--------|
| 1278    | 0.4         | 20–25                  | 42     | 15–20          | M   | Normal    | SIDS            | No                   | NA  | 8      |

HW, heart weight; BW, body weight; LV, left ventricle; NA, not available; RIN, RNA integrity number; RV, right ventricle; SIDS, sudden infant death syndrome; PMI, post-mortem interval.
Fig. 3 | Signature analysis of sSNV reveals mutational processes in cardiomyocytes during aging. **a**, Substitution type for the age-accumulated sSNVs (the ‘net increase’ in sSNVs between infant and aged cardiomyocytes). C > T and T > C substitutions are predominant. **b**, Cardiac mutational signatures identified by NMF based on the trinucleotide context of sSNVs. Each signature is displayed according to the 96 trinucleotide contexts, defined by the six substitution types and sequence context immediately 5′ and 3′ to the mutated base. Although both Signatures A and D predominate with C > T and T > C substitutions, they differ in trinucleotide contexts at C > C substitutions.

**c, d**, Signature-specific sSNV density in cardiomyocytes, neurons, hepatocytes and lymphocytes. Signature D specifically accumulated in aged cardiomyocytes, whereas Signature A accumulated with age in all cell types but at different rates. **d**, NMF-based decomposition of cardiac signatures into COSMIC cancer signatures. The relative contribution of each cancer signature is shown as heatmaps. **e**, Transcription bias of age-accumulated sSNVs. Asterisks mark significant difference between transcribed and untranscribed strands (two-tailed Poisson test) in cardiomyocytes (C > G, \( P = 4.7 \times 10^{-5} \); T > A, \( P = 1.2 \times 10^{-4} \); T > C, \( P < 2.2 \times 10^{-16} \); T > G, \( P < 2.2 \times 10^{-16} \)) and in neurons (C > T, \( P = 7.3 \times 10^{-4} \); T > C, \( P = 8.9 \times 10^{-2} \); T > G, \( P = 1.6 \times 10^{-2} \)). Notably, T > C substitution is enriched in the untranscribed strand in cardiomyocytes, whereas it is enriched in the transcribed strand in neurons, suggesting different mutation mechanisms in these two nondividing cells.

**Functional impact of sSNVs in the aging process.** To further investigate whether the occurrence of sSNVs is associated with defective gene transcription and function, we stratified and compared cardiac and neuronal sSNVs by using the expression profiles of corresponding tissues in GTEx. By estimating the mutual signature composition of genic sSNVs in each gene expression quartile and for each age group, we found that Signature A sSNVs are enriched in highly expressed genes at a similar level in both aged cardiomyocytes and aged neurons (Fig. 4c, upper), suggesting Signature A as a common transcription-associated signature\(^5\). In contrast, Signatures C and D showed higher contributions in aged cardiomyocytes than in aged neurons, without a strong association with gene transcription level (Fig. 4c, middle and lower), indicating that Signatures C and D might result from mechanisms distinct from Signature A, and...
Fig. 4 | Potential mechanism of formation of sSNVs and their impact on cardiomyocytes genome during aging. a, mRNA expression level of MMR complex components indicating significant downregulation of MMR genes with increased age in heart samples but not in brain samples (n = 168 donors). Heart versus brain (P = 8.4 × 10⁻⁵, two-tailed paired Wilcoxon test); age effect in heart (P = 0.04, linear regression). Boxplot with whisker denotes minimum, 25%, median, 75% quartiles and maximum. b, Aged heart (n = 5 donors) showing significantly higher oxidative damage than infant heart (n = 5 donors), quantified by 8-OHdG assay (P = 0.008, two-tailed Wilcoxon test). Error bar, ± s.e.m. c, Association of sSNVs with gene expression level. Signature A accumulated more sSNVs in highly expressed genes in both aged cardiomyocytes and neurons (P = 0.09 and 0.004, linear regression). Signatures C and D are dominant in aged cardiomyocytes without significant correlation with gene expression level. n = 10,407 and 19,101 sSNVs of tetraploid cardiomyocytes and neurons. Error bar, ± 95% confidence interval. d, Aged cardiomyocytes showed excess exonic and nonsynonymous sSNVs when compared with germline mutations (two-tailed Fisher’s exact test), suggesting relaxed constraint of negative selection; n = 10,407 and 19,101 sSNVs of tetraploid cardiomyocytes and neurons. Error bar, ± s.e.m. e, Cardiomyocyte-specifically enriched GO categories (FDR-adjusted P < 0.05, permutation test); x axis denotes the enrichment P value for sSNVs in cardiomyocytes and neurons separately. Cardiac sSNVs are enriched in MMR pathways and pathways involved in metabolism and kinase signaling. f, Prediction model for the effect of sSNVs on abundance of KO tetraploid cardiomyocytes (n = 48 cells from 12 donors). The tetraploid model demonstrates a significantly lower KO rate than the diploid model (P = 4.9 × 10⁻¹, two-tailed paired Wilcoxon test), especially in aged hearts, implying the protective impact of polyploidization against deleterious sSNV accumulation. Error bar, ± s.e.m. g, Mechanism of sSNV occurrence in heart and adaptation of cardiomyocyte to the polyploid genome. Cardiomyocytes with increased age show increased level of oxidative stress and ROS. DNA repair pathways including MMR, NER and BER in aged cardiomyocytes might not function effectively to repair this increased load of DNA damage and lead to the accumulation of sSNVs. Cardiomyocytes with higher ploidy can better tolerate the deleterious effect of these mutational burdens.
relatively specific to cardiomyocytes. We found a higher proportion of exonic and non-synonymous mutations in aged cardiomyocytes when compared with germline heterozygous SNVs (Fig. 4d and Extended Data Fig. 8), which could be explained by the relaxed constraint of negative selection in the somatic context. Gene ontology (GO) analysis found that genes involved in mismatch repair, mitochondria organization and phosphatidylinositol 3-kinases (PI3Kinase) pathways showed sSNV enrichment in aged cardiomyocytes (false discovery rate (FDR)-adjusted $P < 0.05$, permutation test; Fig. 4e). More specifically, we observed protein-altering deleterious somatic mutations in kinetic pathway genes of aged cardiomyocytes (Supplementary Table 5), such as WNK2 (ref. 46), TAOK3 (ref. 47) and BAZ1B, which play key roles in the regulation of electrolyte homeostasis, cell signaling survival, proliferation activities, and DNA damage response. Additionally, protein-altering mutations were identified in ZMYM6 (ref. 48) and DOCK6 (ref. 49) that are associated with cytoskeletal organization (Supplementary Table 5).

Although many heterozygous mutations would likely compromise cardiomyocyte function, it is expected that deleterious gene ‘knockout’ (KO) mutations in haploinsufficient genes would be especially damaging if all the alleles are affected, and that there may be a threshold for the accumulation of such KOs above which cardiomyocyte function would deteriorate. Higher ploidy cells with more copies of chromosomes may potentially represent adaptive mechanisms to guard cells against these KO mutations. Therefore, we compared the accumulation of gene KOs in diploid versus tetraploid cardiomyocytes using a prediction model. In this model, at least two coincident deleterious sSNV events in a diploid cell, or four deleterious sSNVs within one gene in a tetraploid cell, cause loss of function. Diploid cardiomyocytes had an average probability of 0.2% of getting one or more genes completely knocked out by age 60 years, with this probability increasing to 1% by age 80 years, implying that a substantial fraction of cardiomyocytes would carry damaging mutations (Fig. 4f). In contrast, tetraploid cardiomyocytes showed a significantly lower probability of gene KO ($P = 4.9 \times 10^{-14}$, two-tailed paired Wilcoxon test), with less than 0.2% of cells with KO genes at age of 80 years (Fig. 4g). These data strongly suggest that tetraploid cardiomyocytes are more effective in averting the loss of gene function caused by age-related mutations (Fig. 4g).

**Discussion**

Our data show that each individual cardiomyocyte has a profoundly distinctive genome, harboring sSNVs accumulated throughout the lifetime. After controlling for the genomic size difference between tetraploid and diploid cells, cardiomyocytes accumulate age-related SNVs at rates higher than neurons and lymphocytes, but similar to hepatocytes. This finding indicates that the heart and liver, two highly metabolically active organs, harbor a higher load of somatic mutations and have the tenacity to become polyploid, potentially to endure oxidative stress. Although the accumulation rates of hepatocyte and cardiomyocyte are similar, cardiomyocyte sSNVs display distinct signatures of mutagenic processes, with a predominant contribution of Signature D that has been associated with defects in the MMR pathway.

Existing literature shows that cardiomyocyte genome ploidies and nuclear counts vary widely across different mammalian species. Polyploidization is a characteristic feature of mammalian cardiomyocytes and can be stress-induced and/or developmentally programmed. Polyploidization not only plays a role in increasing cell size and metabolic output, but also promotes alterations in the transcriptome and metabolome. Polyploidy also frequently confers resistance to environmental stresses not tolerated by diploid cells. Our prediction models show that tetraploid cardiomyocytes have a significantly lower probability of complete gene KO compared with diploid cardiomyocytes, indicating that cardiomyocyte polyploidization potentially offers a mechanism to ameliorate the deleterious effects of this rapid mutation accumulation. Human cardiomyocytes initially are mainly diploid, though tetraploid cardiomyocytes begin to appear soon after birth. The formation of hexaploid, octoploid and potentially higher ploidy cells arises with advanced age.

Our data indicate that aging results in increased generation, decreased repair, or both, of oxidative DNA lesions. Age-related myocardial sSNVs have distinctive $C>A$ mutations, which are hallmarks of oxidative damage, and direct quantification by enzyme-linked immunosorbent assay shows increased oxoguanine in the aged heart. Decomposition of Signature C with COSMIC signature indicates significant contributions of SBS8 and SBS18. This finding strongly suggests that the damaged guanine accumulates either via disrupted BER, linked to SBS8 as well as disrupted BER, linked to SBS18. Most likely these $C>A$ mutations are from the accelerated accumulation of oxidized nucleotides that overwhelm these repair pathways, since our finding from GTEx expression data indicates expression of both NER and BER pathway genes are changed only mildly during heart aging. Oxidized guanine nucleotides reflect the presence of increased ROS, which has previously been associated with various cardiovascular diseases, and can be generated by a variety of processes including inflammation and mitochondrial dysfunction that are well studied in cardiovascular disease. Our findings suggest that increased oxidative stress leads to elevated 8-OHdG, which may overwhelm NER and BER repair machinery, resulting in increased DNA mutational burden. Another mutational signature that is uniquely enriched in cardiomyocytes compared with neurons suggests a role of defective MMR in mutation generation. It is known that failure of DNA MMR is associated with a strikingly elevated rate of base substitution mutations and, as a consequence, tumors with MMR deficiency are amongst those with the highest number of somatic mutations. Our findings of increased sSNV counts in the aged heart suggest that MMR may not be efficient at correcting mismatched nucleotides in aged cardiomyocytes, contributing to the large increase in sSNVs.

Here we show that the number of sSNVs and the likelihood of disrupting essential gene function in human cardiomyocytes increases significantly with age, suggesting that the age-related cellular dysfunction in aged cardiomyocytes could be due partially to somatic mutations, although more studies will be needed to draw a causal relationship between mutational burden and age-associated decrease in cardiac function. We identified a total of 10,407 sSNVs from 48 tetraploid cardiac nuclei by LiRA. Among 75 coding SNVs, 36 were predicted to be damaging (Supplementary Table 5). We also observed seven sSNVs shared by two cardiomyocytes (no sSNVs shared by three or more cardiomyocytes); six of these were shared by cardiomyocytes obtained from the same donor, indicating early somatic mutations in the common lineage of these cardiomyocytes. More comprehensive measurements of somatic mutation from healthy and diseased myocardium will be needed to decipher the functional impact of somatic mutation in aging and heart disease. In this study, we investigated only single nucleotide variants, but cardiomyocytes could also carry other types of somatic mutations, including indels and structural variations. MDA requires extensive quality control to identify well-amplified samples, so that our samples are biased towards cells that amplified well and evenly, that is, cells more likely to have intact genomes. Importantly, the sSNV increase rate in neurons amplified by MDA (19 sSNV per cell genome per year) is consistent with the rate estimated by a recently developed duplex sequencing protocol without genome amplification (20 sSNV per cell genome per year), suggesting the accuracy of MDA-based sSNV analysis. Newer methods, such as primary template amplification (PTA) or META-CS may provide an improved means to study somatic mutations in diploid and multiploid cardiomyocytes with broader genomic coverage for variant calling and better distinction of sSNVs from single-stranded lesions. Nevertheless, these results provide an early view into the mutational landscape...
of terminally differentiated cardiomyocytes. Our analysis of human cardiomyocytes lays a foundation for better understanding of the genomic landscape and mechanisms driving mutation accumulation in aging cardiomyocytes that may help develop new treatments to reduce age-related cardiomyocyte dysfunction.

Methods

Isolation of cardiomyocyte nuclei. Cardiac nuclei were isolated using a density sedimentation protocol. Briefly, 100 μg of cardiac tissue from the left ventricle was homogenized in 5 ml of ice-cold lysis buffer (30 mM sucrose, 5 mM CaCl2, 3 mM magnesium acetate, 2.0 mM EDTA, 0.5 mM EGTA, 10 mM Tris-HCl (pH 8.0) and 1 mM dithiothreitol (DTT)). The suspension was then layered onto a cushion of 3 ml 2.1 M sucrose solution and centrifuged at 30,000g for 1 h at 4°C. The pellet from each tube was then resuspended with 1.5 ml nuclei storage buffer (0.43 M sucrose, 70 mM KCl, 2 mM MgCl2, 10 mM Tris-HCl (pH 7.2) and 5 mM EGTA) for further analysis.

Flow cytometry. Accurate identification of cardiomyocyte nuclei is crucial for the analysis of this study. Single cardiac nuclei were isolated using FANS-based cardiac troponin T staining and nuclear DAPI intensity, using FACSAria (20 psi, 100-mm nozzle, Becton Dickinson Biosciences). Cardiac nuclei were identified using a sequential gating strategy. Initial size gates for FSC versus SSC were set to select the large cardiac nuclei with high FSC and SSC corresponding to larger and more granular cells. Cell doublet discrimination was performed by a combination of high forward scatter height and area FSC-H/FSC-A and SSC-H versus SSC-W plots. H versus W or A allows separating the doublets from the single-cells containing 4n amounts of DNA. Cells containing 4n amounts of DNA have double the A and H values whereas W is roughly the same as cells containing 2n and 4n amounts of DNA. Cardiomyocytes are a cardiac tissue so ploidy is a convenient way to purify them. However, to rule out any possibility that tetraploid cells accumulate mutations in different ways from diploid cells, or that the amplification, sequencing and calling process performs differently in tetraploid cells, we carried out replicate analysis of diploid cells using isolating diploid cardiomyocytes using cardiomyocyte-specific markers (cardiac troponin T). The genomes of every single nucleus were amplified using MDA.

Ploidy quantification by imaging flow cytometry and karyotyping. We used a FlowSight Imaging Flow Cytometer to combine the advantages of traditional flow cytometry and microscopy to verify the cardiac nuclei ploidy. Left ventricular cardiomyocyte nuclei were isolated and stained with Hoechst (Invitrogen, catalog no. H3570; 1:1,000) and the cardiomyocyte marker cardiac troponin T (Abcam, catalog no. ab56357; 1:250). The nuclei were resuspended in PBS at a concentration of 2 x 10^8 cells/ml^-1. The DNA content was detected by a FlowSight Imaging Flow Cytometer (Luminex), equipped with a x20 objective lens, and analyzed by image analysis software (IDEAS). The percentage of 2n, 4n and greater than 4n ploidy was determined by setting gates using the calibration with nuclei of noncardiomyocytes at 2n. The software separated the cardiomyocyte nuclei using brightfield, Hoechst and Troponin T images.

Chromosomes were visualized by Giemsa staining (GIBCO KaryoMAX Giemsa Stain Stock Solution, catalog no. 10992-013) according to the manufacturer’s protocol. Briefly, sorted cardiac nuclei from 1465 were treated with a hypotonic solution (0.075 M KCl) and preserved in their swollen state with Carnoy’s fixative; further nuclei were dropped on to slides and air-dried. The slides were stained with freshly prepared Giemsa staining solution (3:1 ratio of Gurr Buffer and Giemsa Stain) and visualized at x100 magnification.

Expression analysis of sorted cardiac nuclei. ddPCR assays were performed to test the cardiomyocyte-specific gene expression by using Tagman probe of PLN (Hs01841144), TNNT2 (Hs00943911), MYH7 (Hs0110632), CD31 (Hs0169777_m1) and PGDFB (Hs01019589). QX100 Droplet Digital PCR System (Bio-Rad) was used with standard parameters. We measured numbers of droplets that were positive and negative for each gene using QuantaSoft software.

Library preparation and WGS. We sequenced 48 tetraploid and 8 diploid single cardiac nuclei from 12 individuals with ages from 0.4 to 82 years, including three infants (<4 years), six middle-aged (30–66 years) and three aged (>75 years) individuals (Table 1). From each of the 12 individuals, we sequenced four single cardiac nuclei. Low coverage library preparations were carried out according to the manufacturer’s instructions (QIAseq FX single-cell DNA Kit). MDA-amplified DNA libraries were prepared with the Illumina TrueSeq Nano LT sample preparation kit. Bulk DNA was extracted using the QIAamp DNA Mini kit with RNase A treatment. Paired-end sequencing (150 bp x 2) was performed on a HiSeq X Ten instrument. Single-cell and bulk WGS library preparations were done at Macrogen Genomics. The sequencing depth of cardiomyocytes was comparable with that of neurons we previously studied (Extended Data Fig. 9).

Read alignment and postprocessing. Reads generated from single-cell WGS were aligned against the GRC37 human reference genome by BWA (v0.7.15) with default parameters. Duplicate reads were marked by Mark Duplicate of Picard (v2.8) and then postprocessed with local realignment around indels and base quality score recalibration using Genome Analysis Toolkit (GATK) (v3.5).

Measuring the evenness of genome amplification in single-cells. We measured the evenness of genome amplification in single-cells using two metrics: MAPD and CoV. MAPD is the median value of absolute differences between the copy number ratio among variable lengths, where we decided to have the same number of uniquely mapping reads. CoV is the measure of variance of bin-wise copy number ratios, calculated by taking the ratio of their standard deviation to the mean. Both higher MAPD and CoV scores represent greater unevenness of single-cell genome amplification. Binning, GC normalization, segmentation and copy estimation were performed following the previous single-cell copy number analysis protocol23, to obtain the copy number ratio per bin and calculate MAPD and CoV scores.

Estimation of amplification dropout rates in single-cell WGS data. Germline heterozygous SNVs were identified from bulk WGS data using HaplotypeCaller of GATK with default parameters (+stand_call_conf 30.0 -ploidy 2)24, and only those reported by the 1000 Genomes Project were considered subsequently as high-confidence variants to estimate dropout rate. For each single-cell, a germline heterozygous SNV was considered as locus dropout if the total coverage in single-cell WGS is less than five times and considered as allelic dropout if the number of reads supporting either a reference or a mutant allele is less than two. The genome-wide locus- and allele-dropout rates were then calculated as the proportions of dropout sites among all germline heterozygous SNVs.

Somatic SNV calling from single-cell WGS data. We performed phasing-based linked read analysis using the LiRA method (v0.2018 Feb)20 to identify sSNVs in single-cell in tetraploid cells using variable lengths, where we decided to have the same number of uniquely mapping reads. LiRA distinguishes true somatic mutations from base-calling or amplification errors by leveraging the linkage information between the somatic candidate and adjacent phased germline mutations. For each single-cell, the threshold for number of phasable reads supporting mutant allele was calculated to control for more than 90% true positive rate. The detection sensitivity in phasable regions was estimated from germline SNVs and then used to adjust the LiRA-detected sSNV count to the real count. sSNV density per megabase was calculated for each single-cell with the consideration of doubled genomic size for tetraploid cardiomyocytes. We considered sSNVs in autosomes only to avoid potential detection bias in sex chromosomes between different genders.

Somatic SNV burden correction for tetraploid cells. Each tetraploid cardiomyocyte contains two sets of diploid genomes (that is, four haplotypes). Theoretically, somatic mutations present in one out of the four haplotypes can be called by LiRA only when the reads violating complete linkage were lost due to allelic or locus dropout (Extended Data Fig. 10a). In comparison, germline mutations can be called in the same way as in the diploid cells. Therefore, the LiRA-estimated power from germline SNVs should be corrected by cell-specific allelic or locus dropout rates before applying to the count of identified sSNVs in tetraploid cells.

Theoretically, the dropout status of a site in a tetraploid cell (S_d) was determined by the status of its two diploid origin cells (Extended Data Fig. 10b). A locus dropout happened in a tetraploid cell only when both of its diploid origin cells were locus dropout, whereas an allelic (reference or mutant allele) dropout happened in a tetraploid cell when two copies of the corresponding alleles from two diploid origin cells were lost by locus or allelic dropout. Using simulated
tetraploid cells by an in silico mixture of single-cell WGS data from two diploid cells from the same individual, we observed that the locus dropout rate in simulated tetraploid cells generally equals the product of the dropout rates in the two original diploid cells, suggesting independence of dropout occurrences across the genome between MDA-amplified cells.

Cell-specific allelic and locus dropout rates were estimated for each tetraploid cell, and the dropout rate for its two diploid origins was then calculated from the above matrix under the assumption of equal rates between the two diploid origins. The contributions of LiRa-called sSNVs were further adjusted to the locus and allelic dropout rate of the corresponding diploid origins and the sensitivity loss due to the decrease of per-haplotype sequencing depths from diploid to tetraploid cells.

**Mutational signature analysis.** Mutational signatures were decomposed de novo by the NMF-based mutational signature framework5 using MutationalPatterns (v.1.8.0), using the same tetraploid contexts of sSNVs detected from tetraploid cardiomyocytes in this study as well as nondisease neurons that were previously studied8. For most of the downstream analyses, except the regression modeling of sSNV density where we used all neurons to cover the whole age span, only neurons from the same donors of the studied cardiomyocytes were considered to better control for potential background. We estimated signature stability and reconstruction error and found that four signatures best fit the observed sSNV profiles (Extended Data Fig. 4). We then compared our de novo signatures (Signatures N1, N2, N3 and N4) with previously reported signatures in neurons (Signatures A, B and C)10 and found that four signatures best fit the observed sSNV profiles (Extended Data Fig. 4). As shown in Extended Data Fig. 5, Signatures N1, N2 and N3 resembled Signatures A, B and C (as well as SBS scf). A and C, respectively, whereas Signature N4 did not show high similarity to any of these signatures, suggesting a potential cardiac-specific signature (renamed as Signature D).

To remove the potential contamination of MDA artifacts, we decomposed the sSNV profile of each single-cell into Signatures N2/A, N3/C, N4/D as well as SBS scf and SBS scE (SBS scF) using MutationalPatterns. We then calculated the signature-specific sSNVs density for each single-cell by multiplying the overall sSNV density and the cell-specific weight for each signature. The contributions of SBS scf and scE were subtracted from the overall sSNV density for subsequent burden analyses.

**Burden and list of sSNVs in hepatocytes and lymphocytes.** Genome-wide sSNV burden and list of MDA-amplified hepatocytes and lymphocytes profiled by single-cell WGS were extracted from Brazhnik et al.19 and Zhang et al.36, respectively. The contributions of SBS scf and scE were estimated and subtracted from the overall sSNV burden for each hepatocyte and lymphocyte, following the same strategy as that performed in each cardiomyocyte and neuron.

**Mixed-effects modeling of somatic SNV density.** To study the age-dependent somatic mutation accumulation and the rate difference between cardiomyocyte and other cell types, we performed linear mixed-effects regression modeling using the lme4 (< 3.1.23) and ImerTest (< 3.1.2) R packages. Overall and signature-specific burden of sSNVs per gene was modeled as a fixed effect, whereas donor and cell type were modeled as random effects, because cells from the same donor and cell type may share the biological environment and thus be independent in terms of sSNV density. The maximum likelihood method was used to fit linear mixed-effects regression models.

To test the age effect of sSNV density in healthy individuals, we fitted the model $y_{ij} = \beta_0 + \beta_1 \times \theta_{ij} + \beta_2 \times \theta_{ij} + \epsilon_{ij}$, where $y_{ij}$ is the sSNV density in cell $i$ from donor $j$, $\beta_0$ is the fixed effect of age, $\beta_1$ is the age of donor $j$, $\mu$ is the number of sSNVs at birth, $\theta_0$ is the random effect of each donor following a normal distribution with mean 0 and variance $\sigma_0$, $\epsilon_0$ is the measurement error of each cell following a normal distribution with mean 0 and variance $\sigma_\epsilon$. We observed a significant age-association of sSNV density in tetraploid cardiomyocytes ($P = 7.3 \times 10^{-6}$, Fig. 3a), and further confirmed similar sSNV densities between tetraploid and diploid cardiomyocytes (Extended Data Fig. 2a).

To test the difference in the age effect between different cell types, we fit the model $y_{ijk} = \beta_0 + \beta_1 \times \rho_{ij} + \mu + \theta_{ij} + \epsilon_{ij}$, where $y_{ijk}$ is the sSNV density in cell $i$ from cell type $k$ of donor $j$, $\beta_0$ is the fixed effect of age, $\rho_{ij}$ is the fixed effect of cell type $k$ on age (interaction terms between age and cell type), $\rho$ is the age of donor $j$, $\mu$ is the number of sSNVs at birth, $\theta_{ij}$ is the random effect of the donor-cell type pair following a normal distribution with mean 0 and variance $\tau$, and $\epsilon_{ij}$ is the measurement error of each cell following a normal distribution with mean 0 and variance $\sigma_e$. As shown in Fig. 2c, we observed that cardiomyocytes showed an age effect that was significantly larger than neurons and lymphocytes ($P = 5.0 \times 10^{-6}$ and $6.7 \times 10^{-7}$, respectively) for each cell type. The transcriptional strands of genomic sSNVs were assigned based on the UCSC TxDb annotations by MutationalPatterns17, where mutated bases (‘C’ or ‘T’) on the same strand as the gene direction were categorized as ‘transcribed’ and on the opposite strand as ‘transcribed’. To characterize sSNV accumulation during aging, we further estimated the mutation spectrum and strand bias for the net increase of sSNVs between infant and aged categories. Specifically, we first measured the absolute sSNV count for each mutation type by multiplying its proportion and the average sSNV burden for each age category, and then subtracted the sSNV count for each mutation type between infant and aged categories. The statistical significance of strand bias was determined by the Poisson test.

**Gene expression analysis.** The expression matrix ‘Gene read counts’ (GTEx Analysis v8) for left ventricle of the heart and frontal cortex (BA9) of the brain was downloaded from the GTEx portal, since these two regions are the corresponding source tissues for our single-cell cardiomyocytes and neurons, respectively. The per-gene expression value was then normalized for each tissue sample after estimating sample-specific size factor and dispersion as well as modeling tissue, age and gender factors using DESeq2 (ref. 42) (v.1.24.0) with the recommended protocol and default parameters. To study the age-dependent changes in MMR activity in the heart and brain, we extracted the expression levels of core components of the MMR complex (MLH1, MLH3, MSH2, MSH3, MSH6, PMS1, PMS2) as well as genes in the NER and BER pathways annotated by the KEGG database. We included individuals with both heart and brain expression profiles, and then the quartile classification was performed according to their ages. Individuals with ages less than 40 years and more than 70 years were excluded due to the small sample size ($n < 10$). For the remaining 168 individuals, we calculated the average expression levels of the MMR, NER and BER genes in heart and brain samples, separately, and tested their association with age using simple linear regression models.

To investigate the relationship between somatic mutation and gene expression, we assigned genes into four quartiles based on their average expression values in heart or brain samples across all GTEx individuals. Cardiac and neuronal sSNV densities were calculated for each quartile of genes, after normalizing by gene length and per-cell sSNV detection power. The standard deviation of sSNV density was calculated by using a permutation test, in which the quartile classification of genes was shuffled randomly and the permuted sSNV densities were calculated for 1,000 rounds. We further performed an NMF-based mutational signature decomposition for sSNVs located in each quartile of genes, to estimate the relative contributions of Signature A, Signature C, Signature D, SBS scf and scE for each quartile. The SSNV density for each signature was calculated by multiplying the overall sSNV density by the signature contribution. We also performed the above analysis by using the expression profiles from aged individuals (> 75 years) only and observed robust results.

**Functional enrichment analysis.** GO functional enrichment analysis was performed using GOSeq (v.1.34.1). We assigned a binary value of 0 or 1 to each RedGene according to whether the sSNV was present in the gene in any single-cell and built the sSNV-gene table for cardiac and neuronal sSNVs separately. GOSeq uses the Wallenius approximation method to test the enrichment of sSNVs for each GO term, after applying a probability weighting function to control for potential bias from gene length. Genes without any GO annotation were ignored when calculating the total gene count. GO terms with fewer than five member genes with sSNVs were excluded to avoid ascertainment bias. GO terms with more than 1,000 member genes were also excluded.

To identify GO terms that were specifically enriched in cardiomyocytes but not in neurons, we performed a permutation test among all GO terms with $P < 0.01$ for either cardiac or neuronal sSNVs. For each permuted GO term, we compared the observed rank difference in GOseq’s P between cardiac and neuronal sSNVs against the expected null distribution, which was estimated by 1,000 rounds of random shuffling of the sSNV-gene tables. The FDR method was applied for correcting multiple hypothesis testing.

**Measurement of oxidative stress.** The level of 8-OHdG and 8-oxo-Gua was measured in 250 ng total nucleic acids extracted from left ventricular cardiomyocytes using a competitive enzyme-linked immunosorbent assay kit (Cayman Chemical, catalog no. 589320) according to the manufacturer’s instructions. The samples were incubated for 1 h with a monoclonal antibody tagged with horseradish peroxidase in a microplate (P=0.5 for 8-OHdG and P=0.03 for 8-oxo-Gua). The final color was developed by the addition of 3,3,5,5-tetramethylbenzidine, and absorbance was measured at 450 nm. The samples were diluted at 1:50 with enzyme immunoassay buffer before assaying.

**Modeling accumulation of gene KOs in cardiomyocytes.** Accumulation of exonic, deleterious gene KO mutations might be detrimental to proper cell function. These mutations can be ‘biallelic’ in the case of diploid cells, or ‘quadallelic’ in the case of tetraploid cells. The number of sSNVs identified in this
study were used to estimate the accumulation of gene KO's in single-cells, using an extension of the method described in Lodato et al.7. To account for genes that are highly dosage sensitive, and thus can be haploinsufficient, we included a factor to capture the probability of a mutation landing on an allele of a gene with a high pLI score. The pLI metric measures the probability of loss-of-function intolerance6, and genes with pLI score greater than 0.90 are considered highly dosage sensitive. These high pLI score genes comprise 17% of all genes. Consequently, the calculation was computed as follows:

\[
n = \text{number of estimated sSNV's} \times \frac{\text{total number of deleterious variants}}{\text{total number of variants}} \times p
\]

\[
d_i = \begin{cases} 1 & \text{event that gene i has at least one mutation} \\ x_i & \text{event that gene i has a high pLI score} \end{cases}
\]

\[
D = \text{probability of a gene having a deleterious mutation}
\]

\[
Pr(KO|\pi, D, n) = \pi \times (1 - (1 - D_i^{-1})^n) + (1 - \pi)(1 - e^{-\alpha D})
\]

where \( p \) is the ploidy factor that captures the probability of obtaining a mutation on the remaining alleles of the gene (for example, \( p=0.5 \) for diploid genomes, and \( p=0.125 \) for tetraploid genomes) and \( n \) is the expected number of deleterious mutations. Considering the similar sSNV density but half genomic size in diploid cardiomyocytes when compared with tetraploid cardiomyocytes (Extended Data Fig. 2), the genome-wide sSNV burden in diploid cardiomyocytes of each individual was calculated as 50% of the burden in corresponding tetraploid cardiomyocytes. The mean and s.e.m. were calculated across all cells per individual, for tetraploid and diploid cardiomyocytes separately. Regressions were performed using an exponential model to capture the nonlinear trend of the probability of obtaining cells with KO genes with age. All calculations were performed using custom R scripts.

**Reporting summary.** Further information on research design is available in the Nature Research Reporting Summary linked to this article.

**Data availability**

Single-cardiomyocyte WGS data is deposited in the NCBI dbGaP with accession number phs002264.v1.p1. The data are available under controlled use conditions set by human privacy regulations. Other data are available upon request.

**Code availability**

The code used in this study is available upon reasonable request to the corresponding authors.

Extended Data Fig. 1 | See next page for caption.
Extended Data Fig. 1 | Isolation and identification of cardiac nuclei. 

**A**, Representative immune-histochemical detection of cTroponin T in cardiomyocyte nuclei. Section from non-diseased human left ventricle tissue stained against cTroponin T and the nuclear marker DAPI demonstrating nuclear labeling in cardiomyocytes. Scale bar, 20 μm. 

**B,C**, Purity check of fluorescence-activated sorted cardiomyocyte nuclei. ddPCR analysis (n = 4 experiments for 12 cases) of tetraploid cardiac nuclei (B), and cTroponin T+ve diploid cardiac nuclei (C). Both tetraploid and cTroponin T positive diploid cardiomyocytes are highly enriched for PLN and TNNT2, cardiac markers, but not PDGFB or CD31, markers for fibroblast and endothelial cells. Each lane represents 1 single nucleus, except the first lane, containing 100 nuclei. The bottom clusters on the plot represent the negative droplets and the upper clusters represent the droplets that are positive for the respective reference assay.
Extended Data Fig. 2 | Comparison of sSNV burden between tetraploid and diploid cardiomyocytes for total mutations (A) and per-signature mutations (B–F). Except for the SBS scF mutations in infant cardiomyocytes, there were no statistically significant differences ($p > 0.05$, two-tailed Wilcoxon test) in the mutation burden between tetraploid ($n = 12$ for infant and aged each) and diploid ($n = 4$ for infant and aged each) cardiomyocytes. Boxplot with whisker denotes minimum, 25%, median, 75% quartiles, and maximum.
Extended Data Fig. 3 | Evaluation of sSNV burden in cardiomyocytes with the consideration of amplification evenness or non-C>T mutations.

A, Uncorrected sSNV density of tetraploid cardiomyocytes. B–C, sSNV density of tetraploid cardiomyocytes after correcting for two metrics about amplification evenness, MAPD (B) and CoV (C). D, sSNV density of tetraploid cardiomyocytes after excluding C>T mutations. Tetraploid cardiomyocytes showed consistent age-dependent accumulation of sSNVs, robust to amplification evenness ($p = 3.9 \times 10^{-4}$ for MAPD correction and $1.3 \times 10^{-3}$ for CoV correction, mixed-effects model) and the exclusion of C>T mutations ($p = 3.3 \times 10^{-5}$, mixed-effects model).
Extended Data Fig. 4 | Signature metrics for de novo mutational signature analysis. De novo mutational signature analysis was performed using non-negative matrix factorization (NMF), in which the factorization rank is critical to define the number of signatures used to decompose the target matrix of sSNVs. We identified that four signatures can maximize the cophenetic and best fit the observed sSNV matrix.
Extended Data Fig. 5 | Comparison of mutational signatures identified in this and other studies. (Left panel) De novo mutational signatures identified from single human cardiomyocytes in this study. (Middle panel) Previously published signatures identified from single human neurons (Lodato et al.). (Right panel) Recently published signatures thought to represent artifacts of single-cell whole genome amplification, SBS scE and scF, from a study of cultured cells (Petljak et al.). Signature D/N4 was present only in cardiomyocytes but not in neurons. Signature B/N1 identified in cardiomyocytes and neurons resembles the artifact signature SBS scF, thus it was excluded for further mutational burden and signature analyses in this study.
**Extended Data Fig. 6 | Hierarchical clustering between cardiac and COSMIC cancer signatures.** Unsupervised clustering was performed among single-cardiomyocyte-derived signatures (Signatures A, C, and D) and cancer-derived COSMIC signatures (SBS1-60), by using cosine similarity of 96-class of trinucleotide context to measure the pairwise distance. Signature A resembles SBS5 and Signature D resembles SBS44.
Extended Data Fig. 7 | mRNA expression level of NER (A) and BER (B) pathway genes in the GTEx heart and brain samples (n = 186 donors). Heart vs. brain (p = 3.7 × 10^{-15} and 1.9 × 10^{-15} for NER and BER, two-tailed paired Wilcoxon test); age effect in heart (p = 0.04 for BER, linear regression). Boxplot with whisker denotes minimum, 25%, median, 75% quartiles, and maximum.
Extended Data Fig. 8 | Distribution of sSNVs across different categories of genic annotation (A) and mutation type (B). sSNVs identified from tetraploid cardiomyocytes (n = 10,407) and neurons (n = 19,101) were grouped according to the age group of donors. Error bar, mean ± 95%CI.
Extended Data Fig. 9 | Sequencing depth and down-sampling performance for cardiomyocytes and neurons. **A**, No systematic difference in sequencing depth ($p = 0.51$, two-tailed Wilcoxon test) between tetraploid cardiomyocytes ($n = 48$) and neurons ($n = 155$). Eight outlier cardiomyocytes (in the dashed rectangle) were intentionally sequenced at doubled sequencing depth from two donors. Boxplot with whisker denotes minimum, 25%, median, 75% quartiles, and maximum. **B**, LiRA-estimated sSNV burden remained generally robust with varied sequencing depths at or above the average depth in neurons, denoted by the dashed line. Four outlier cardiomyocytes from **(A)** were randomly chosen, and their sequencing reads were *in silico* down-sampled into 25%, 50%, and 75% of the original sequencing depths. Error bar, mean ± 95%CI.
Extended Data Fig. 10 | See next page for caption.
Extended Data Fig. 10 | Model for calling sSNVs from diploid and tetraploid cells by LiRA. 

A, In diploid cells, LiRA identified the complete linkage between each sSNV candidate and its adjacent germline heterozygous mutation, which distinguishes true sSNVs from technical artifacts. In tetraploid cardiomyocytes, sSNVs present in one out of the four haplotypes were able to be called by LiRA when the reads violating complete linkage were lost due to allelic or locus dropout. 

B, Dropout status of a tetraploid cell determined by its two diploid origin cells. Rows and columns denote the dropout status of two diploid origin cells, respectively. mut-allele, mutant allele of the germline mutation; ref-allele, reference allele of the germline mutation.
Reporting Summary

Nature Portfolio wishes to improve the reproducibility of the work that we publish. This form provides structure for consistency and transparency in reporting. For further information on Nature Portfolio policies, see our Editorial Policies and the Editorial Policy Checklist.

Statistics

For all statistical analyses, confirm that the following items are present in the figure legend, table legend, main text, or Methods section.

- The exact sample size (n) for each experimental group/condition, given as a discrete number and unit of measurement
- A statement on whether measurements were taken from distinct samples or whether the same sample was measured repeatedly
- The statistical test(s) used AND whether they are one- or two-sided
  - Only common tests should be described solely by name; describe more complex techniques in the Methods section.
- A description of any covariates tested
- A description of any assumptions or corrections, such as tests of normality and adjustment for multiple comparisons
- A full description of the statistical parameters including central tendency (e.g. means) or other basic estimates (e.g. regression coefficient) AND variation (e.g. standard deviation) or associated estimates of uncertainty (e.g. confidence intervals)
- For null hypothesis testing, the test statistic (e.g. F, t, r) with confidence intervals, effect sizes, degrees of freedom and P value noted
  - Give P values as exact values whenever suitable.
- For Bayesian analysis, information on the choice of priors and Markov chain Monte Carlo settings
- For hierarchical and complex designs, identification of the appropriate level for tests and full reporting of outcomes
- Estimates of effect sizes (e.g. Cohen’s d, Pearson’s r), indicating how they were calculated

Our web collection on statistics for biologists contains articles on many of the points above.

Software and code

Policy information about availability of computer code

- Data collection: No collection software was used.

- Data analysis: BWA (ver 0.7.15) was used to align sequencing reads to the GRCh37 human reference genome (with decoy); Picard (ver 2.8) was used to mark duplicate reads; GATK (ver 3.5) was used for indel realignment, base quality recalibration, and germline and raw somatic SNV calling; Shapeit 2 (ver 904) was used for haplotype phasing; LIRA (ver 2018Feb) was used for sSNV calling and burden estimation; R package MutationalPatterns (ver 1.8.0) was used for mutational signature and strand bias analyses; ANNOVAR (ver 2015Mar22) was used for SNV annotation; R package DEseq2 (ver 1.24.0) was used for GTex expression analysis; R package GQseq (ver 1.34.1) was used for GO enrichment analysis.

For manuscripts utilizing custom algorithms or software that are central to the research but not yet described in published literature, software must be made available to editors and reviewers. We strongly encourage code deposition in a community repository (e.g. GitHub). See the Nature Portfolio guidelines for submitting code & software for further information.

Data

Policy information about availability of data

All manuscripts must include a data availability statement. This statement should provide the following information, where applicable:
- Accession codes, unique identifiers, or web links for publicly available datasets
- A description of any restrictions on data availability
- For clinical datasets or third party data, please ensure that the statement adheres to our policy

Single-cardiomyocyte whole genome sequencing data is deposited in the NCBI dbGaP with accession number phs002284.v1.p1. The data are available under controlled use conditions set by human privacy regulations.
Field-specific reporting

Please select the one below that is the best fit for your research. If you are not sure, read the appropriate sections before making your selection.

☑ Life sciences  ☐ Behavioural & social sciences  ☐ Ecological, evolutionary & environmental sciences

For a reference copy of the document with all sections, see nature.com/documents/nr-reporting-summary-list.pdf

Life sciences study design

All studies must disclose these points even when the disclosure is negative.

Sample size: We studied 56 single cardiomyocytes from 3 young, 6 middle-age and 3 aged individuals to establish the sSNV-age association and perform genomic characterization. Sample size were chosen commensurate with the numbers necessary to detect effects in previous study of normal aging of neurons (Science 2018 Feb 2;359(6375):555-559. doi: 10.1126/science.aao4426. Epub 2017 Dec 7)

Data exclusions: All cardiomyocytes with high coverage whole genome sequencing are presented in the study, no data was excluded.

Replication: To improve reproducibility, we performed experiments on multiple cardiomyocytes from each case, each experiments were performed multiple times with success.

Randomization: Randomization is not relevant to this study. Our study did not involve case/control, or treatment group, covariates were controlled by considering them in our regression model.

Blinding: Investigators were not formally blinded. Data were analyzed as a group, such that uniform analyses were performed on different age groups.

Reporting for specific materials, systems and methods

We require information from authors about some types of materials, experimental systems and methods used in many studies. Here, indicate whether each material, system or method listed is relevant to your study. If you are not sure if a list item applies to your research, read the appropriate section before selecting a response.

Materials & experimental systems

| n/a | Involved in the study |
|-----|-----------------------|
| ☐   | ☑ Antigens            |
| ☑   | Eukaryotic cell lines |
| ☑   | Palaeontology and archaeology |
| ☑   | Animals and other organisms |
| ☑   | Human research participants |
| ☑   | Clinical data         |
| ☑   | Dual use research of concern |

Methods

| n/a | Involved in the study |
|-----|-----------------------|
| ☑   | ChIP-seq              |
| ☑   | Flow cytometry        |
| ☑   | MRI-based neuroimaging |

Antibodies

Antibodies used: anti-cardiac troponin T (Abcam, EP1106Y, AlexaFluor-488 conjugated, 1:1250), anti PCM1 (Atlas, HPA023374, 1:200)

Validation: anti-cardiac troponin T and PCM1 reactivity validated by the company for human. Validated by the company for FACS.

Human research participants

Policy information about studies involving human research participants

Population characteristics: We selected 12 individuals, 6 males and 6 females, for single cardiomyocyte whole-genome sequencing. Three infant (<4 yrs), six middle-age (30-66 yrs), and three aged individuals (>75 yrs).

Recruitment: Tissue was obtained from UMB NIH Neurobiobank.

Ethics oversight: This study was approved by the Boston Children’s Hospital IRB.

Note that full information on the approval of the study protocol must also be provided in the manuscript.
Flow Cytometry

Plots

- The axis labels state the marker and fluorochrome used (e.g., CD4-FITC).
- The axis scales are clearly visible. Include numbers along axes only for bottom left plot of group (a ‘group’ is an analysis of identical markers).
- All plots are contour plots with outliers or pseudocolor plots.
- A numerical value for number of cells or percentage (with statistics) is provided.

Methodology

Sample preparation

Cardiac nuclei were isolated utilizing a density sedimentation protocol. Briefly, 100 mg of cardiac tissue from the left ventricle were homogenized in 5 mL of ice cold lysis buffer (0.32 M sucrose, 5 mM CaCl₂, 3 mM magnesium acetate, 2.0 mM EGTA, 0.5 mM EDTA, 10 mM Tris-HCl (pH 8.0), and 1 mM DTT). The suspension was further dounced (twenty strokes) with a type A pestle in a glass douncer (Sigma). The homogenized solution was filtered through 100 and 70 μm strainer (Pulsiriselect) and centrifuged for 7 min at 700 g at 4 °C and the crude nuclear pellets were resuspended in 2.1 M sucrose solution (2.1 M sucrose, 3 mM magnesium acetate, 1 mM DTT, and 10 mM Tris-HCl, pH 8.0). This was then layered onto a cushion of 5 mL 2.1 M sucrose solution and centrifuged at 30,000 g for 1 hr. at 4 °C. The pellet from each tube was then resuspended with 1.5 mL of nuclei storage buffer (0.43 M sucrose, 70 mM KCl, 2 mM MgCl₂, 10 mM Tris-HCl (pH 7.2), and 5 mM EGTA) for further analysis.

Instrument

FACSARia, Becton Dickenson Biosciences,

Software

Flowjo, 10.7.1.

Cell population abundance

Left ventricular cardiomyocyte nuclei were isolated and stained with DAPI (Thermo Scientific, 62248, 1:1000) and the cardiomyocyte marker cardiac troponin T (Abcam ab56357 1:500). The nuclei were resuspended in PBS at a concentration of 2 x 10⁷ cells/mL. The percentage of 2N, 4N, and >4N ploidy was determined by setting gates using the calibration with nuclei of calf thymocyte nuclei (BD: 349523).

Gating strategy

The gating strategy is explained in figure 1A,B and DC. Cardiac nuclei were identified using a sequential gating strategy. Initial size gates for forward scatter (FSC) vs. side scatter (SSC) were set to select the large cardiac nuclei with high FSC and SSC corresponding to larger and more granular cells. Cell doublet discrimination was performed by a combination of high forward scatter height and area FSC-H/FSC-A and SSC-H vs. SSC-W plots. Height vs. width or area allows to separate the doublets from the single-cells containing 4n amounts of DNA. Cells containing 4n amounts of DNA have double the area and height values whilst the width is roughly the same as cells containing 2n amounts of DNA. Cardiomyocytes are the only tetraploid cell in cardiac tissue, so ploidy is a convenient way to purify them. Diploid cardiomyocytes were isolated using cardiomyocyte-specific markers (cardiac troponin T).

Tick this box to confirm that a figure exemplifying the gating strategy is provided in the Supplementary Information.
