We present a numerical study of a quantum phase transition from a spin-polarized to a topologically ordered phase in a system of spin-1/2 particles on a torus. We demonstrate that this non-symmetry-breaking topological quantum phase transition (TOQPT) is of second order. The transition is analyzed via the ground state energy and fidelity, block entanglement, Wilson loops, and the recently proposed topological entropy. Only the topological entropy distinguishes the TOQPT from a standard QPT, and remarkably, does so already for small system sizes. Thus the topological entropy serves as a proper order parameter. We demonstrate that our conclusions are robust under the addition of random perturbations, not only in the topological phase, but also in the spin polarized phase and even at the critical point.

I. INTRODUCTION

A quantum phase transition (QPT) occurs when the order parameter of a quantum system becomes discontinuous or singular\(^1\). This is associated with a drastic change of the ground state wave function. Unlike classical phase transitions, QPTs occur at \(T = 0\) and thus are not driven by thermal fluctuations. Instead, quantum fluctuations are capable of changing the internal order of a system and cause the transition. When a quantum Hamiltonian \(H(\lambda)\), which depends smoothly on external parameters \(\lambda\), approaches a quantum critical point \(\lambda_c\) from a gapped phase, the gap \(\Delta\) above the ground state closes, and the critical system has gapless excitations. This corresponds to a continuous, second order QPT.

Here, we consider a QPT from a spin polarized to a topologically ordered phase: a topological quantum phase transition (TOQPT). The internal order that characterizes topologically ordered phases cannot be explained by the standard Ginzburg-Landau theory of symmetry breaking and local order parameters. Instead, it requires the notion of Topological Order (TO)\(^2\). TO manifests itself in a ground state degeneracy which depends on the topology of the physical system, and it is robust against arbitrary local perturbations\(^3\). This robustness is at the root of topological quantum computation, i.e., the ground state degeneracy can be used as a robust memory, and the topological interactions among the quasi-particles can be used to construct robust logic gates\(^4\). On the other hand, to what extent a TOQPT is affected by perturbations is a problem that has only very recently been addressed\(^5\), and is a focus of this work. Moreover, the classification of TO is still an open question. Ground state degeneracy, quasiparticle statistics and edge states, all measure and detect TO but do not suffice to give a full description. Tools from quantum information theory, specifically entanglement\(^6\) and the ground state fidelity\(^7\), have recently been widely exploited to characterize QPTs. To date, all the QPTs studied with these tools have been of the usual symmetry breaking type. Here we apply them to the transition from a spin-polarized phase to a TO phase, and find that they are universal in the sense that they detect this transition. However, these tools do not suffice to distinguish a symmetry breaking QPT from a TOQPT.

Specifically, we present an exact time-dependent numerical study of a TOQPT, introduced in Ref.\(^8\), from a spin-polarized phase to a TO phase, for both the ideal model and the model in presence of an external perturbation. Our results are the following: (i) standard QPT detectors (derivative of the ground state energy\(^9\), entanglement of a subsystem with the remainder of the lattice\(^10\), ground state fidelity\(^11\)) are all singular at the critical point of the TOQPT, thus confirming that this is indeed a QPT. Ground state fidelity and block entanglement are thus capable of dealing also with non symmetry breaking QPTs. (ii) \(S_{\text{top}}\) detects the TOQPT in a very sharp manner already for small system sizes. It also detects TO better than other non-local order parameters, in particular the expectation value of Wilson loops. It is therefore appropriate for the detection and characterization of TOQPTs and for studying TO. These results complement and strengthen the conclusions of Ref.\(^8\). (iii) Adiabatic evolution can initialize topological quantum memory faithfully: even in the presence of perturbations the coupling to other topological sectors and excited states is negligible. (iv) This robustness extends to the entire topological phase, and even to the critical point itself. Perturbations do not affect the nature of the TOQPT either.
a TOQPT:
\[ H_0(\tau) = H_U + \tau H_g + (1 - \tau)H_\xi, \]  

where \( H_\xi \equiv -\xi \sum_{\tau=1}^n \sigma_0^\tau, \tau = t/T \in [0, 1], \) and \( T \) is the total time. The non-degenerate ground state of \( H(0) = H_U + H_\xi \) is the spin polarized state \(|\text{vac}\rangle\) which is the vacuum of the strings. The term \( (1 - \tau)H_\xi \) acts as a tension for the strings, whereas \( \tau H_g \) causes the strings to fluctuate. As \( \tau \) increases, the string fluctuations increase while the loop tension decreases. For a critical value of \( \lambda = \tau g/(1 - \tau)\xi \), and in the thermodynamic limit, a continuous QPT occurs to a TO phase of string condensation. This QPT is not symmetry breaking, i.e., is a TOQPT. As argued in Ref.\(^\text{2}\), provided \( T \gg 1/\Delta_{\text{min}} \) (the minimum gap, as a function of \( \tau \), between the ground state and the first excited state) evolution according to \( H(\tau) \) is an adiabatic preparation mechanism of a TO state: one of the \( 2^{2^g} \) degenerate ground states of Kitaev’s toric code model\(^\text{12}\). Ref.\(^\text{2}\) showed that \( \Delta_{\text{min}} \sim 1/\sqrt{n} \). \( H(\tau) \) can be mapped onto an Ising model in a transverse field, which is known to have a second order QPT (see also\(^\text{10}\)). However, in this work we do not resort to such a mapping, because it is non-local and does not preserve entanglement measures. Instead, we numerically study \( H(\tau) \) for \( \tau \in [0, 1] \) in \( \Delta \tau = .01 \) increments on lattices \( L_n \) with \( n = \{8,18,32\} \) spins, and set \( U = 100, \xi = g = 1 \). The computational methods used here are (i) the Housholder algorithm\(^\text{13}\) for the full diagonalization (all eigenstates) of \( L_8 \), and (ii) a modified Lanczos method\(^\text{14}\) to obtain the low-energy sectors of \( L_{16} \) and \( L_{32} \). We observe that for all \( \tau \in [0, 1] \) the ground state comprises only closed strings. Since this is the case for every finite system size, and in order to reduce computation cost, we diagonalize \( L_{32} \) only in the relevant symmetry subspaces, defined by the constraint \( A_s|\psi\rangle = \prod_{j \in s} \sigma_j^z |\psi\rangle = |\psi\rangle, \forall s \).

II. PRELIMINARIES

Consider a square lattice \( L \) with periodic boundary conditions (torus) and with \( n \) spin-1/2 degrees of freedom occupying its vertices. The Hilbert space is given by \( H = \text{span}\{|0\rangle, |1\rangle\}^\otimes n \), where \( |0\rangle \) and \( |1\rangle \) are the \( \pm \) eigenvectors of the Pauli \( \sigma_z \) matrix. As shown in Fig. 1D, the \( n \) plaquettes can be partitioned into two sub-lattices, denoted by different colors. Following Kitaev, we associate with every white plaquette \( p \) an operator \( B_p = \prod_{j \in p} \sigma_j^z \) that flips all spins along the boundary of \( p \). A “closed string operator" is a product of plaquette operators \( B_p \) that flips all spins around a loop (or around a loop net). The “group of closed strings" \( X \) is the group of products of plaquettes \( B_p \). Similarly, with every pink plaquette \( s \), we associate an operator \( A_s = \prod_{j \in s} \sigma_j^z \) which counts if there is an even or odd number of flipped spins around the plaquette \( s \). Kitaev’s toric code Hamiltonian\(^\text{4}\) is then given by \( H_{U,g} = -U \sum_s A_s - g \sum_p B_p \equiv H_U + H_g \), which realizes a \( Z_2 \) lattice gauge theory in the limit \( U \rightarrow \infty \). The ground state is an equal superposition of all closed strings (loops) acting on the spin polarized state \(|\text{vac}\rangle \equiv |0\rangle_1 \otimes \ldots \otimes |0\rangle_n \) — it is in a string-condensed phase. The ground state manifold is given by \( L = \text{span}\{|X|^{-1/2}(t_{1}^\tau)^{(t_{2}^\tau)} \prod_{x \in X} x|\text{vac}\rangle; \ i, j \in \{0, 1\}\} \), which is fourfold degenerate\(^\text{4,14}\). The \( t_{1,2}^\tau \) flip all the spins along an incontractible loop around the torus (See Fig. 1D), taking a vector in \( L \) to an orthogonal one in the same manifold because they commute with \( H_{U,g} \). On a lattice on a Riemann surface of genus \( g \), there are \( 2g \) incontractible loops \( \{t_{j}^\tau \} \), and therefore \( L \) is \( 2^{2g} \)-fold degenerate\(^\text{4,14}\) (for a torus \( g = 1 \)).

The Model and the QPT. — Now consider the following time-dependent Hamiltonian, introduced in\(^\text{12}\) as a model for
FIG. 2: (Color online) Fidelity between the time-dependent solution of the Schrödinger equation and the adiabatic state, for different values of the total evolution time: $T = 20, 40, 60$. (a) The unperturbed model for L18. The evolution is adiabatic for $T = 60$. Note that the drop in adiabaticity is a precursor of the QPT. (b) L8: fidelity in both the ideal and perturbed ($P = 1$) cases. The perturbed model is indistinguishable from the ideal one.

IV. ADIABATIC EVOLUTION

We numerically simulated the time evolution from the fully polarized state at $\tau = 0$ to the string-condensed phase at $\tau = 1$. The possibility of preparation of topological order via such evolution has been studied theoretically in Ref. 6. A crucial point is to show that the adiabatic time depends on the minimum gap that marks the phase transition (and that is polynomially small in the number of spins), and not on the exponentially small splitting of the ground state in the topological phase. To this end, one must show that transitions to other topological sectors are forbidden and protected by topology. The initial wave function is the exactly known ground state of $H(\tau = 0)$. This state is then used as the seed to compute the ground state of $H(\Delta \tau)$. After iteration, this state is in turn used as the seed for $H(2\Delta \tau)$, etc. We can estimate to what extent the evolution is adiabatic by numerically solving, for L18, the time dependent Schrödinger equation $H\psi(\tau) = i\dot{\psi}(\tau)$ for different values of the total evolution time $T$. This is shown in Fig. 2a, where we plot the fidelity between the time evolved wave function $\psi(\tau)$ and the instantaneous ground state: $F_{\text{ad}} = |\langle \psi(\tau) | \psi_0(\tau) \rangle|$. Moreover, we compute $F_{\text{ad}}$ also for the perturbed model, but the largest lattice for which we can do this is L8. Fig. 2b shows clearly that for $P = 1$ the perturbation does not change the time-evolved state. Significant effects start at $P \geq 2$ (not shown). We also find that the overlap between the evolved wave function $\psi(\tau)$ and the other sectors $(l_{xi}^j (l_{zi}^j) | \psi_0(\tau) \rangle$ is of order $\sim 10^{-3}$ for every $(i, j) \neq (0, 0)$ and value of $T$ tested. This is numerical evidence for the argument that time evolution will always keep the instantaneous eigenstate within a topological sector, even in presence of perturbations. Thus the relevant gap for adiabatic evolution is that to the other closed string excited states, which implies that the evolution into the TO sector can be used to prepare a topological quantum memory. Henceforth we work only in the sector $(i = 0, j = 0)$, into which the system is initialized as the unique ground state of $H(\tau = 0)$.

V. DETECTING THE QPT WITH STANDARD MEASURES

To check that the transition from magnetic order to TO is indeed a QPT, we first computed the energy per particle of the ground state for L8, L18, L32, and its second derivative. As seen in Fig. 3a, the latter develops a singularity as system size increases, signaling a second order QPT with a critical point at $\tau \approx 0.71$, corresponding to a ratio $\xi/g \sim 0.41$. This is in good agreement with the analytical study, which obtained (in the thermodynamic limit) $\xi/g \sim 0.44$, even if this model is only asymptotically equivalent to the toric code in a magnetic field, in the small field limit. On the other hand, Ref. 2 found $\xi/g \sim 0.33$, using a mapping to the classical 3D Ising model. In Fig. 3b we show the block entanglement between four spins in a small loop (B11, Fig. 1) and the rest of the lattice, as measured by the von Neumann entropy. In agreement with the general theory, the derivative of the entanglement diverges at the critical point for a second order QPT.

A new interesting characterization of QPTs can be given in terms of the scaling in the fidelity $F_{\Delta \tau}(\tau) = |\langle \psi(\tau) | \psi(\tau - \Delta \tau) \rangle|$ between different ground states. A quantum phase transition, the fidelity should scale to zero superextensively. Previous work has shown that the fidelity criterion is valid for generic symmetry breaking second order QPTs. Nevertheless, the fidelity criterion is not strictly local, so one would like to know whether it detects the QPT to a topologically ordered state. The results are shown in Fig. 3c. The fidelity drop criterion indeed also detects the QPT. Figures 3a)-(c) also show the result for the perturbed model.

By looking at the behavior of the transition in the presence of perturbations, we can safely conclude that the QPT is unaffected by the perturbation for $P \leq 10$, namely the value of $\tau_c$ and the magnitude of the fidelity drop remain unchanged. In Fig. 3d, we plot the overlap between the perturbed and unperturbed ground state. The drop in this quantity also signals the QPT, showing that the system is most sensitive to perturbations at the critical point (see also Ref. 2). Interestingly, in contrast to the robustness of the entanglement and $F_{\Delta \tau}(\tau)$, the perturbed and unperturbed ground states differ significantly already for $P > 2$. The results in Fig. 3 thus allow us to infer unambiguously that there is indeed a second order QPT in the adiabatic dynamics generated by $H(\tau)$. However, none of the quantities shown in Fig. 3 is explicitly designed to detect topological features, and hence these quantities are incapable of distinguishing between a symmetry breaking QPT and a TOQPT.

VI. CHARACTERIZING THE TOPOLOGICAL PHASE

The spin-polarized regime for $\tau < \tau_c$ is characterized by a finite magnetization. On the other hand, the topologically ordered phase $\tau > \tau_c$ does not admit a local order parameter. The topologically ordered phase is a string condensed phase...
the model and its QPT against perturbations: (a) Second derivative of $E(\tau)$, diverging for $\tau_c \sim .7$. The QPT is thus second order. (b) Derivative of the von Neumann entropy, measuring the entanglement of a plaquette with the rest of the lattice. Its divergence at criticality also signals a second order QPT. The perturbation has no effect for $P = 20$ (triangles indistinguishable from circles) but is visible for $P = 40$. (c) Ground state fidelity $F(\tau)$: the fidelity drop at the critical point signals a QPT, associated with a drastic change in the properties of the ground state. (d) Overlap between the perturbed for $\psi(\tau - \delta)$ and the ideal ground state. The clearly visible susceptibility to the critical point signals a QPT, associated with a drastic change in the properties of the ground state. (d) Overlap between the perturbed

FIG. 4: (Color online) Expectation value of Wilson loop operators of increasing size for $L32$. The expectation value of the loop operators starts to increase at $\tau_c$, more steeply so for the largest loops, indicating that this observable can be used to detect the TOQPT for large systems.

FIG. 3: (Color online) QPT detectors for $L8$, $L18$, $L32$, for the unperturbed and perturbed model. All graphs show strong resilience of the model and its QPT against perturbations: (a) Second derivative of $E(\tau)$, diverging for $\tau_c \sim .7$. The QPT is thus second order. (b) Derivative of the von Neumann entropy, measuring the entanglement of a plaquette with the rest of the lattice. Its divergence at criticality also signals a second order QPT. The perturbation has no effect for $P = 20$ (triangles indistinguishable from circles) but is visible for $P = 40$. (c) Ground state fidelity $F(\tau)$: the fidelity drop at the critical point signals a QPT, associated with a drastic change in the properties of the ground state. (d) Overlap between the perturbed

and an effective $Z_2$ local gauge theory and thus the observables must be gauge invariant quantities. These quantities are the Wilson loops. In this theory, we make a Wilson loop $W^{x(z)}[\gamma]$ of the $x(z)$ type by drawing a closed string $\gamma$ on the lattice, and operating with $\sigma^x(\sigma^z)$ on all the spins encountered by the loop. In the polarized phase, the tension is high and it is difficult to create large loops. The expectation value of loops decays with the area enclosed by the loop. In the topologically ordered phase, large loops are less costly and their expectation value only decays at most with the perimeter of the loop. The phase transition is of the confinement/deconfinement type. We can write any (contractible) Wilson loop as the product of some plaquette operator: $W^{x(z)}[\gamma] = \prod_{B \in S} B_\gamma$. In particular at the point $\tau = 1$ when the model is the exact toric code, the expectation value of Wilson loops is $\langle W^{x(z)}[\gamma] \rangle = 1$ for every loop $\gamma$, independently of its size. Of course, large loops are highly non-local observables. We have computed the expectation value of Wilson loop operators of increasing size as a function of $\tau$. As Fig. 4 shows, the expectation values of large loops vanish in the spin-polarized phase, and increase exponentially in the TO phase. However, in the limit of infinite length, Wilson loops are not observables of the pure gauge theory and cannot be measured.

Nevertheless, topological order reveals itself in the way the ground state is entangled. If we compute the von Neumann entropy for a region with perimeter $L$, the entanglement entropy will be $S = L - 1$ in the topological phase – see Fig. 4. The spin polarized phase is not entangled. We see that there is a finite correction of $-1$ to the boundary law for the entanglement, which is due to the presence of topological order. Therefore we can consider as an alternative non local order

FIG. 5: (Color online) von Neumann entropy for a plaquette of spins and $S_{\text{top}}$ for $L32$ with an Ising Hamiltonian in a transverse field. Note the different vertical scales. For a system without topological order, $S_{\text{top}}$ is always $\sim 0$. (the small bump is a finite-size effect).
FIG. 6: (Color online) $S_{\text{top}}$ for $L18$ and $L32$, and von Neumann entropy for $L32$, for the ideal and perturbed model. $S_L$ assumes the value $l-1=3$ in the entire TO phase, where $l-1$ is the exact value of $S_L$ for the pure Kitaev model ($\tau=1$) and $l=4$ is the length of the border of a plaquette. $S_{\text{top}}$ is zero in the spin-polarized phase and quickly reaches unity in the TO phase. Also the topological character of the QPT and of the phases is resilient to perturbations.

FIG. 7: (Color online) First derivative of $S_{\text{top}}$ for $L18$ and $L32$, for the ideal and perturbed model, diverging at $\tau_c$, thus signaling the TOQPT; (inset) derivative and full width at half maximum of $S_{\text{top}}$ at $\tau_c$, as function of perturbation strength $P$. $S_{\text{top}}$ remains robust up to $P \sim 25$.

The block entropy in Fig. 6 shows that the state is already rather entangled in the spin-polarized region, whereas $S_{\text{top}}$ is almost zero before the transition to TO occurs. Note that the block entropy at the critical point is bounded from above by the final-state entanglement ($\tau=1$), which obeys the area law. This is an example of the fact that in 2D, critical systems do not need to violate the area law as in 1D. The useful feature of $S_{\text{top}}$ is not only that it can be used in order to locate the critical point [Fig. 7], but also that it allows one to understand the type of QPT (symmetry breaking or TO). Remarkably, Figs. 5,7 show that $S_{\text{top}}$ has these properties already for finite and very small systems. The accuracy of the finite-size $S_{\text{top}}$ at the limit points $\tau=0,1$ is due to the fact that there the correlations are exactly zero-ranged. This, however, is not the case for intermediate $\tau$, especially near the QPT, so how $S_{\text{top}}$ works as an order parameter, and how sharply its derivative detects the QPT, are rather non-trivial.

In the presence of the perturbation $h^\tau(j)$, which tends to destroy the loop structure, $S_{\text{top}}$ detects the TOQPT up to the value $P \sim 25$, after which a transition occurs: see Fig. 7 (inset). Overall, Figs. 6,7 show that the robustness of TO against perturbations is a feature of the whole topological phase and not only of the analytically solvable model at $\tau=1$. Finally, we note another remarkable fact: setting the $x$-perturbation $V$ to zero, and moving backward in time from $\tau=1$, we can view also the tension term $H_\xi$ as a perturbation. This is due to the fact that the toric code is symmetric under the exchange $x \leftrightarrow z$ in the spin components. The flatness of $S_{\text{top}}$ in Fig. 6 (squares and circles) shows the robustness of the topological phase against this perturbation (see also Ref. 2).

VII. CONCLUSIONS

We have presented a comprehensive numerical study of a TOQPT. Our results show, using a variety of previously proposed QPT detectors, that this is a second order transition.
Unlike the other detectors, the topological entropy $S_{\text{top}}$ is capable of distinguishing this TOPQT from a standard one, already for small lattices. Strikingly, the model and its TO-QPT are highly robust against random perturbations not only deep inside the topological phase, where the gap protects the ground state from perturbations, but – even more surprisingly – at the gapless critical point. This phenomenon requires further investigation to be properly understood. Moreover, $S_{\text{top}}$ detects the TOQPT for perturbations of strength up to 20% of the strongest couplings. Of course finite-size effects can be important, but it is not possible at present to compute $S_{\text{top}}$ exactly without direct diagonalization, and this poses limits on the maximum size of systems that can be studied.
