Background: Evidence suggests a 2.1–4.6 times increase in the risk of violent behavior in schizophrenia compared to the general population. Current theories propose that the processing of negative emotions is defective in violent individuals and that dysfunctions within the neural circuits involved in emotion processing are implicated in violence. Although schizophrenia patients show enhanced sensitivity to negative stimuli, there are only few functional neuroimaging studies that have examined emotion processing among men with schizophrenia and a history of violence.

Objective: The present study aimed to identify the brain regions with greater neurofunctional alterations, as detected by functional magnetic resonance imaging during an emotion processing task, of men with schizophrenia who had engaged in violent behavior compared with those who had not.

Methods: Sixty men were studied; 20 with schizophrenia and a history of violence, 19 with schizophrenia and no violence, and 21 healthy men were scanned while viewing positive, negative, and neutral images.

Results: Negative images elicited hyperactivations in the anterior cingulate cortex (ACC), left and right lingual gyrus, and the left precentral gyrus in violent men with schizophrenia, compared to nonviolent men with schizophrenia and healthy men. Neutral images elicited hyperactivations in the right and left middle occipital gyrus, left lingual gyrus, and the left fusiform gyrus in violent men with schizophrenia, compared to the other two groups.

Discussion: Violent men with schizophrenia displayed specific increases in ACC in response to negative images. Given the role of the ACC in information integration, these results indicate a specific dysfunction in the processing of negative emotions that may trigger violent behavior in men with schizophrenia.

Keywords: schizophrenia, violence, negative emotions, salience, anterior cingulate cortex, fMRI

Introduction

According to the World Health Organization,1 over 21 million people worldwide suffer from schizophrenia. Of particular concern is the evidence showing an increased risk of aggressive and violent behavior (severe assaults, attempted murder, homicide) among people with schizophrenia compared to the general population.2–6 Although most people with schizophrenia are not violent,7,8 individuals suffering from schizophrenia were found to be 2.1–4.6 times more likely to commit a violent crime or engage in violent behavior than the general population, even when taking into account socioeconomic status (SES), comorbid substance use, and personality disorders.2,8,10 In addition to
promoting stigmatization and victimization of all persons with mental health problems, violent behavior by persons with schizophrenia has important consequences for the health and criminal justice systems, as shown by increasing numbers of forensic hospitals, longer periods in hospital, and increased rates of incarceration, all of which increase costs. Given that these consequences added to the suffering of the victims, their families, and the perpetrators, it is imperative to identify the neural mechanisms underlying violence in schizophrenia. A better understanding of these mechanisms would allow the development of effective interventions to prevent violent behavior.

Current theories propose that the processing of negative emotions (fear, anger) is defective in violent individuals. In fact, emotional instability was observed in adult offenders, as well as maladaptive coping with negative affect and oversensitivity to negative stimuli has been reported in aggressive men. Moreover, the processing of negative emotions, especially anger, was shown to be a factor in precipitating violent behavior and aggression. As the processing of negative emotions is important in violence, some postulates about the neural underpinnings of violent behavior have been found in the literature of emotion processing. Considering that negative emotions are processed by a system involving the orbitofrontal cortex, amygdala, and anterior cingulate cortex (ACC), it has been proposed that dysfunctions within this system might be implicated in violence and aggression. Neuroimaging studies of violent individuals have generally supported this assumption. Given the association between negative affect (anger) and violent behavior in psychotic disorders, similar abnormalities in the amygdala–orbitofrontal system might be expected in violent men with schizophrenia (SCZ+V) as in violent men who do not have psychosis. However, these studies are limited by small sample sizes and/or lack of adequate comparison groups, as well as omission of positive emotions from the investigated affects. Even though most theories regarding emotion processing in violence concern negative affect, examining the processing of positive stimuli could be informative as studies have found reward-processing to be impaired in schizophrenia and violent individuals to be especially sensitive to immediate reward. Of further interest, Cohen and Minor have noted that schizophrenia is associated with an aversion to neutral stimuli. Functional magnetic resonance imaging (fMRI) findings show that persons with schizophrenia assign abnormal salience to neutral material. Therefore, it is also important to explore the neural response to neutral stimuli when examining emotional processing in SCZ+V.

Overall, knowledge of emotion processing in SCZ+V is scarce and inconclusive. Using adequate control groups, we sought to identify brain regions with neurofunctional alterations among SCZ+V compared to men with schizophrenia who have no history of violence (SCZ−V) and healthy controls, during an fMRI emotion processing task. Responses to negative, positive, and neutral emotions were assessed.

**Methods**

**Participants**

Thirty-nine male outpatients with schizophrenia or schizoaffective disorder (DSM-IV criteria; age 18–55 years) were recruited from forensic and general psychiatric hospitals. They were divided into two groups: 20 SCZ+V and 19 SCZ−V. In accordance
with the MacArthur study, serious violence was defined as a history of armed aggression resulting in injuries or death. Antecedents of serious violence were assessed based on clinical interview (Structured Clinical Interview for DSM-IV), self-reports (MacArthur Community Violence Instrument), and clinical files. All patients were stabilized on antipsychotic medication that had not changed within the last 2 months. Antipsychotic dosage was calculated using chlorpromazine equivalents. Symptom severity was evaluated with the Positive and Negative Syndrome Scale, which yield five sub-scores (ie, positive, negative, disorganization/cognitive, excitation, depression) according to Lindenmayer et al.’s five-factor model of schizophrenia. Urine drug screenings were administered.

The control group included 21 men with no history of violent behavior. Controls were screened with the nonpatient edition of the Structured Clinical Interview for DSM-IV. All participants were free of concomitant neurological disorders and substance use disorders (lifetime, for controls; in the last 12 months, for SCZ+V and SCZ–V). No participant had an IQ lower than 70 or MRI contraindications. Parental SES was assessed according to the National Occupational Classification. Finally, as in prior studies on violence, we calculated the number of DSM-IV diagnostic criteria for antisocial personality disorder that were met by each participant. The score ranged from no criterion to seven criteria.

Ethical approval
The patients were recruited by clinical staff that they knew. After having the study explained to them, all participants signed a consent form agreeing to interviews, an MRI, and the patients consented to giving access to their medical and criminal files. The study was approved by the local ethics committees from the Regroupement de Neuroimagerie du Québec, the Centre de recherche de l’Institut Universitaire en Santé Mentale de Montréal, and the Institut Philippe-Pinel de Montréal.

Experimental procedure and task
During fMRI, participants viewed blocks of emotionally positive, negative, and neutral pictures from the International Affective Picture System (IAPS). These pictures were matched for content (people, animals, landscapes), visual complexity and color, and grouped based on valence and arousal intensity (using the IAPS normative data), resulting in five experimental conditions: high arousal/positive, high arousal/negative, low arousal/positive, low arousal/negative, and neutral. Each condition was presented in separate blocks lasting 48.5 seconds, interceded by 16-second rest periods. To ensure that participants attended to the images, they were asked to press a button whenever they saw a person in the picture. Each block contained ten images of one specific experimental condition, and each block type (high arousal/positive, high arousal/negative, low arousal/positive, low arousal/negative) was repeated two times (except the neutral block, which was repeated four times). Each picture appeared for 3,000 ms followed by a blank screen with a fixation point for an average of 1.75 seconds (average interstimulus interval 4.75 seconds). The order of presentation of blocks was pseudorandomized. At the end of the fMRI session, participants were asked to rate the photographs in each block, on a scale ranging from 0 (absence of any emotional reaction) to 8 (strongest emotion ever felt in one’s lifetime).

Neuroimaging acquisition parameters
Whole-brain fMRI was performed using an echoplanar imaging sequence measuring blood oxygenation level-dependent (BOLD) signal (TR =3,000 ms; TE =30 ms; FA =90°; matrix =64×64; voxel size =3.5 mm³; 41 slices). The functional slices were oriented in transverse plane and were angled to be parallel to the AC–PC line. An inline retrospective motion correction algorithm was employed while the echoplanar images were acquired. Individual high-resolution coplanar anatomical images were also acquired during the same scanning session (three-dimensional, spoiled gradient echo sequence; TR =19 ms; TE =4.92 ms; FA =25°; matrix size =256×256; voxel size =1 mm³; 176 slices).

Analysis of fMRI data
fMRI data was analyzed with Brain Voyager QX software (Brain Innovation, Maastricht, the Netherlands). Functional images were slice-time-corrected, corrected for motion artifacts (≤2 mm; all fMRI images were usable), high-pass-filtered (two cycles per time course), coregistered to the corresponding anatomical image, spatially normalized to the Talairach space, and spatially smoothed with a 3D isotropic Gaussian kernel (8 mm FWHM).

We used a standard peak detection approach and a general linear model to identify the cerebral changes associated with emotion processing. Five predictors of interest, corresponding to the experimental conditions/blocks, were convolved with the hemodynamic response function estimated using the double-γ model, and a first-order autoregression model was used to account for serial correlations. Initially, a first-level analysis was performed to investigate individual brain activation maps associated with the primary contrasts of interest
([High Negative + Low Negative] > Neutral; orthogonal) ([High Positive + Low Positive] > Neutral; orthogonal). The (Neutral > Rest) contrast was also examined. A second-level random-effects model was then computed to investigate the pattern of activations during emotion processing comparing the three groups. Between-group differences in clinical variables were considered as covariates in fMRI group comparisons.

The statistical threshold for significance was determined by Monte Carlo simulation. Assuming a voxel-level threshold of $P<0.001$ (10,000 simulations), a cluster size of 343 mm$^3$ was required to correct for multiple comparisons at $P<0.05$. When relevant, we identified common activations between contrasts by performing spatial conjunction analyses, using the “Volume of Interest” option of Brain Voyager. For each cluster found to significantly differ between groups in the spatial conjunction analyses, the individual changes in BOLD signal (e.g., $\beta$-values) were extracted and used to visually display results and to perform correlation analyses between regional BOLD responses and clinical variables (e.g., emotional ratings, antisocial traits) within subgroups.

### Statistical analysis of the clinical data

For continuous data, between-group differences were examined using analyses of variances. Pair-wise comparisons were performed using Tukey’s HSD tests. For dichotomic data, $\chi^2$ tests were used. For pair-wise comparisons, Bonferroni correction was applied.

### Results

#### Characteristics of the participants

Table 1 presents comparisons of the three groups of participants. No differences were detected in age, handedness, and ratings of positive and negative images (all $P$-values > 0.05). SCZ+V had lower parental SES than controls ($P=0.013$). SCZ participants, with and without violent behavior, did not differ as to primary diagnoses (schizophrenia vs schizoaffective disorder), age of onset, illness duration, negative symptoms, chlorpromazine equivalents, and the proportion of SCZ patients treated with clozapine (all $P>0.05$). However, SCZ+V presented fewer positive and disorganized symptoms than SCZ−V ($P<0.010$ and $P=0.010$, respectively). Finally, SCZ+V assigned more emotional significance to neutral images than controls, but this result did not achieve significance ($P=0.07$), and there was no significant difference between schizophrenia subgroups ($P>0.05$).

#### Groups comparisons of neural activity during presentation of negative pictures

As presented in Table 2, for the Negative minus Neutral contrast, relative to SCZ−V, SCZ+V showed increased activations in the lingual gyrus, the right middle frontal gyrus, the right inferior frontal gyrus, the bilateral globus pallidus, the

| Table 1 Characteristics of participants | SCZ+V (n=20) | SCZ−V (n=19) | Healthy controls (n=21) | Significance |

**Note:** Significant results are shown in bold ($P<0.05$). *SCZ−V > controls ($P<0.05$).

**Abbreviations:** PANSS, Positive and Negative Syndrome Scale; 5A, schizoaffective disorder; SCZ+V, schizophrenia with violent behavior; SCZ−V, schizophrenia without violent behavior; SE, standard error; SES, socioeconomic status (a higher number indicates a lower SES).
right precuneus, the anterior and mid-cingulate gyrus, and the left precentral gyrus. Relative to controls, SCZ+V showed increased activations in the right fusiform gyrus, the right superior frontal gyrus, the anterior cingulate gyrus, the left lingual gyrus, and the left precentral gyrus. Finally, relative to controls, SCZ−V had decreased activations in temporal, parietal, paralimbic, and cerebellar regions (Table 2).

Conjunction analyses
Since SCZ+V had increased activations compared to SCZ−V and controls, spatial conjunction analyses were performed to identify neural differences common to both group comparisons. As illustrated in Table 3, spatial conjunction analyses revealed four intersections between the “SCZ+V minus SCZ−V” and the “SCZ+V minus Controls” contrasts, namely the right lingual gyrus, the left lingual gyrus, the anterior cingulate gyrus, and the left precentral gyrus (Figure 1). Hyperactivations in these clusters remained significant after controlling for positive and disorganized symptoms, clozapine, and parental SES. Among participants with SCZ, no significant correlations were observed between regional brain activity and subjective ratings of negative images and antisocial personality traits (all P-values >0.05).

### Table 2 Between-group differences in brain activations during viewing of negative emotion pictures

Abbreviation: BA, Brodmann area.
Contrast: Negative > Neutral
(Spatial conjunction between SCZ+V > SCZ–V and SCZ+V > HC)

Notes: The figure displays the four intersections between (SCZ+V > SCZ–V) and (SCZ+V > HC) comparisons (*T-value for the highest peak within the cluster to significantly differ between groups; *P*, 0.001; cluster threshold 343 mm³). Results for SCZ+V > HC comparison are displayed in blue, and for the SCZ+V > SCZ–V comparison in orange. Bar graphs refer to means and SEMs.

Abbreviations: A, anterior; BOLD, blood oxygen level dependent; HC, healthy controls; P, posterior; R, right; SCZ+V, schizophrenia patients with violent behavior; SCZ–V, schizophrenia patients without violent behavior; SEM, standard error of the mean.

Figure 1 Spatial conjunction analyses for the Negative minus Neutral contrast.
Groups comparisons of neural activity during presentation of positive pictures

For the Positive minus Neutral contrast, no differences were observed between SCZ+V and SCZ−V, or between SCZ−V and controls. Relative to controls, SCZ−V had decreased activations in the left lingual gyrus/cerebellar culmen (x =−15; y =−31; z =−14; t =3.8; P<0.001; 571 voxels). Among the participants with SCZ, no significant correlations were observed between regional brain activity and subjective ratings of positive images, and antisocial personality traits (all P-values >0.05).

Groups comparisons of neural activity during presentation of neutral pictures

As presented in Table 4, for the Neutral minus Rest contrast, relative to SCZ−V, SCZ+V showed increased activations in the right inferior temporal gyrus, the bilateral middle occipital gyrus, the medial frontal gyrus, and the left cerebellar tuber. Relative to controls, SCZ+V displayed increased activations in the right middle frontal gyrus, the right and medial superior frontal gyrus, the bilateral superior temporal gyrus, the right superior parietal gyrus, the right cuneus, the left caudate nucleus, the left postcentral gyrus, the left lingual gyrus, and the left inferior occipital gyrus. Relative to controls, SCZ−V showed increased activations in the left inferior parietal gyrus (Table 3).

Conjunction analyses

As illustrated in Table 5, spatial conjunction analyses revealed four intersections between the “SCZ+V minus SCZ” and the “SCZ+V minus Controls” contrast, namely the right middle occipital gyrus, the left lingual gyrus, the left middle occipital gyrus, and the left fusiform gyrus (Figure 2). Hyperactivations in these clusters remained significant after controlling for positive and disorganized symptoms, clozapine, and parental SES. Among participants with SCZ, no significant correlations were observed between regional brain activity and subjective ratings of neutral images, and antisocial personality traits (all P>0.05).

Results of within-group contrasts (Negative > Neutral; Positive > Neutral) are provided in Tables S1 and S2.

Discussion

This is the first study to identify neural alterations in the processing of negative and neutral emotions among men with schizophrenia and a history of violent behavior as compared.

### Table 4 Between-group differences in brain activations during viewing of neutral images

| Brain region | BA | Talairach coordinates | Voxels (mm^3) | Max T* |
|--------------|----|------------------------|---------------|--------|

Notes: *T*-value for the highest peak within the cluster to significantly differ between groups; P<0.001.

Abbreviation: BA, Brodmann area.
to men with schizophrenia and no history of violent behavior and healthy nonviolent men. Negative pictures elicited hyperactivations in SCZ+V relative to SCZ−V and healthy controls in the ACC, the right and left lingual gyrus, and the left precentral gyrus, regardless of arousal intensity. During viewing of neutral stimuli, hyperactivations in SCZ+V were relative to SCZ−V and controls in the left and right middle occipital gyrus, the left lingual gyrus, and the left fusiform gyrus. To our knowledge, this is the first study to report that SCZ+V attribute a higher intensity of experienced emotion to neutral stimuli than healthy controls, a result consistent with similar observations previously made in nonpsychotic individuals with antisocial behavior.57 Regarding positive stimuli processing, we did not observe activations that distinguished SCZ+V from either SCZ−V or healthy controls. However, when viewing positive emotion pictures, SCZ+V showed decreased activations in the left lingual gyrus compared to healthy controls.

The most important finding of the current study is the increase in the ventral ACC reactivity to negative stimuli specifically observed in SCZ+V. The cingulate cortex is crucial in integrating input from many different sources,58 and recent studies suggest that the ACC, subdivided into ventral/rostral/affective and mid/dorsal/cognitive regions, is key for the integration of negative affect and cognitive control.59,60 Indeed, a meta-analysis of fmRI studies suggested that ventral ACC is associated with the generation of emotion, and the dorsal ACC with emotion regulation.61 Furthermore, due to important connections with both the amygdala and the orbitofrontal cortex, the ACC appears to be involved in violent behavior as well.23 Considering the role of the ACC in emotion processing,22,59 the results of the current study suggest that ventral ACC dysfunctions are associated with negative stimuli processing in SCZ+V. A meta-analysis that included 450 SCZ−V reported reduced activity in ACC in relation to emotion processing and emotional experience.62 These latter results might reflect a hyperactivation of the ACC during the viewing of emotionally neutral stimuli, as SCZ−V have been reported to assign abnormal salience to neutral stimuli.42,44 Nevertheless, the results of the current study show that ACC hyperactivations distinguished SCZ−V from the two other groups. Based on the extant literature, dysfunctions in the prefrontal lobe, amygdala, or subcortical nuclei might have been expected in SCZ+V.16,37,38 Negative stimuli did elicit activations in the amygdala in the SCZ+V group, although they were not significantly different from the activations elicited in the other two groups. Given that the amygdala is associated with the automatic detection of threat63 and that the ACC is associated with the integration of information,58 our results might indicate that there is a dysfunction in more elaborate emotion processing among SCZ+V. Evidence shows that negative emotions may be a factor in precipitating violent behavior. The current findings provide a potential mechanistic explanation for this documented clinical observation.22

We also observed a potential influence of image valence on the activity of regions associated with early visual detection (lingual gyrus, fusiform gyrus, middle occipital gyrus) and movement planning (precentral gyrus) in SCZ+V. Activations in the visual cortex during the viewing of emotional stimuli have been frequently reported.64 It has been suggested that early processing might be enhanced as a means of providing advantage in information processing to specific emotional stimuli (aversive, appetitive).65 It is noteworthy that negative and neutral stimuli elicited hyperactivations in the left lingual gyrus in SCZ+V relative to SCZ−V and healthy controls, whereas positive stimuli elicited a hypoactivation of the same region in SCZ+V compared to healthy controls. This pattern, specific to SCZ+V, appears to be an attentional bias in early visual detection as a function of valence, which might indicate that visual emotional stimuli are processed differently in this population. Further studies are needed to investigate whether, in fact, this effect is associated with violence. Finally, the hyperactivation of the left precentral gyrus elicited by negative stimuli might indicate an action/motor preparation.66

This study has certain limitations. Participants in both SCZ+V and SCZ−V groups were taking antipsychotic medications, which could confound the results. However, the potential effects of antipsychotics on the neural correlates of emotion processing are highly inconsistent.42,67,70 Moreover, no group differences were detected in chlorpromazine-equivalent dose, and chlorpromazine equivalents did not correlate with brain activity. Further, the proportions of participants with...
Figure 2 Spatial conjunction analyses for the Neutral minus Rest contrast.

Notes: The figure displays the four intersections between (SCZ+V > SCZ−V) and (SCZ−V > HC) comparisons (*T-value for the highest peak within the cluster to significantly differ between groups; P = 0.001; cluster threshold 343 mm^3). Results for SCZ−V > HC comparison are displayed in blue, and for SCZ+V > SCZ−V comparison in orange. Bar graphs refer to means and SEMs.

Abbreviations: A, anterior; BOLD, blood oxygen level dependent; HC, healthy controls; P, posterior; R, right; SCZ+V, schizophrenia patients with violent behavior; SCZ−V, schizophrenia patients without violent behavior; SEM, standard error of the mean.
SCZ receiving clozapine did not differ between groups, and clozapine had no significant influence on results. This lack of effect of clozapine may be explained by the fact that the brain regions found to be altered here (eg, anterior cingulate and occipital) are not the ones the most consistently affected by clozapine (eg, striatum). 71 SCZ+V presented fewer positive symptoms than SCZ−V. However, our results remained significant when we entered this potential confound in the analyses. Previous studies have shown that elevated levels of positive symptoms are associated with violence. 72,73 In fact, positive psychotic symptoms constitute the principal factor associated with violence during an acute psychotic episode, as does a long duration of untreated psychosis. 74 Once patients are stabilized on antipsychotic medications and present low levels of positive symptoms (<3 on the Positive and Negative Syndrome Scale), neither violent behavior nor other forms of psychosocial functioning are associated with positive symptoms. 75 SCZ+V were characterized by lower parental SES relative to healthy controls, which is consistent with a recent meta-analysis suggesting that low SES might be a risk factor for violence in psychosis. 76 We performed analyses of covariances and found that parental SES did not influence the main results. In this study, we did not recruit a group of nonpsychotic violent individuals. Even though we did not observe an effect of antisocial personality on our results, the inclusion of a group of nonpsychotic individuals with violent or antisocial behavior would have eased the interpretation of our findings. In nonpsychotic individuals with violent or antisocial behavior, reductions in ACC volumes were reported in some studies, while others have not confirmed these findings. 77 A few functional neuroimaging studies have observed abnormal ACC activations in violent/antisocial and nonpsychotic individuals during emotion processing; however, activations were reduced rather than increased. 77–79 Taken together, the available evidence makes it difficult to determine if our results are explained by an effect of violence or by an interaction between psychosis and violence. 80 Finally, although IAPS images are well validated for the study of emotional valence and arousal, 52 the images present in our study and our experimental design were not optimized to investigate discrete emotions such as anger. The study was characterized by several strengths including relatively large samples of men with schizophrenia who underwent detailed assessments of all disorders including substance use disorders, symptoms, and violent behavior. Finally, objective measures showed that no participant had been using substances prior to the brain scan.

Conclusion
To conclude, this is the first fMRI study to investigate the processing of positive, negative, and neutral stimuli among men with schizophrenia and a history of violence. A potential bias toward image valence in early visual detection was observed among SCZ+V. More importantly, these men displayed ventral ACC dysfunctions when processing negative stimuli. Given the role of the ACC in information integration, these results potentially indicate a dysfunction in more elaborate processes related to emotions among SCZ+V. Future studies are needed to investigate the influence of discrete emotions (anger) and emotion regulation on the ACC of this population.
