Objective: To present a case of intralabyrinthine schwannoma (ILS) presenting as Ménière’s disease diagnosed via 4-h delayed gadolinium-enhanced three-dimensional fluid-attenuated inversion recovery magnetic resonance imaging (3D-FLAIR MRI) and treated successfully using the translabyrinthine approach.

Patient: A patient who was diagnosed with intravestibular ILS.

Interventions: The patient underwent comprehensive preoperative neurological examinations and MRI. The tumor was resected using the translabyrinthine approach and was pathologically confirmed as schwannoma based on the surgical specimen.

Main outcome measures: Preoperative audiogram and vestibular test findings and MRI images.

Results: Preoperatively, pure-tone audiogram showed progressive sensorineural hearing loss only on the affected side. The video head impulse test and vestibular evoked myogenic potential test showed vestibular dysfunction on the affected ear. Immediate gadolinium-enhanced T1-weighted MRI revealed an enhanced region in the vestibule. Meanwhile, magnetic resonance cisternography showed a filling defect. Delayed 3D-FLAIR MRI revealed a signal void in the scala media of the cochlea indicative of cochlear hydrops, and a strong signal in the perilymph at the basal cochlea suggestive of impaired blood–labyrinthine barrier.

Conclusion: Delayed 3D-FLAIR MRI is useful in diagnosing concurrent ILSs and endolymphatic hydrops.

Delayed 3D-FLAIR MR imaging, endolymphatic hydrops (EH), intralabyrinthine schwannomas (ILSs), intravestibular schwannoma, vestibular evoked myogenic potential (VEMP), video head impulse test (vHIT), Ménière’s disease
Introduction

Vestibular schwannomas (VSs) are benign neoplasms commonly arising from the Schwann cells of the vestibular division of the vestibulocochlear nerve. Intralabyrinthine schwannomas (ILSs) are a rare clinical entity, and they arise from the distal branches of the vestibular and cochlear nerves within the membranous labyrinth (1, 2). The common symptoms of ILSs are unilateral hearing loss, tinnitus, imbalance/dizziness and occasionally episodes of vertigo, which are similar to those of Ménière’s disease (MD) (3, 4). Endolymphatic hydrops is a characteristic of MD and other inner ear diseases, such as endolymphatic tumors. Moreover, VSs can cause endolymphatic hydrops (5–9). Naganawa et al. developed magnetic resonance imaging (MRI) methods to facilitate the visualization of endolymphatic hydrops in living humans using intravenous gadolinium-based contrast media (10, 11). Herein, we report a case of concurrent ILS mimicking MD and cochlear hydrops diagnosed via gadolinium-enhanced MRI.

Case report

A woman in her 30’s visited our department due to hyperacusis in the right ear. Audiogram showed almost normal hearing level (Figure 1A). The patient did not present with spontaneous or positional nystagmus. However, she occasionally experienced vertigo in the morning 4 years prior to her initial visit to our department. Four years after the first visit, she presented with vertigo, tinnitus, and hearing loss in the right ear. Audiogram revealed moderate right sensorineural hearing loss particularly at low frequencies (Figure 1B). Magnetic resonance (MR) cisternography showed no VS in the cerebellopontine angle. However, a filling defect of fluid intensity was detected in the vestibule of the right ear, and this finding was overlooked by an otolaryngologist and a radiologist (Figure 2A asterisk). Corticosteroid was prescribed for 7 days for acute sensorineural hearing loss in the right ear. Thereafter, partial hearing improvement was observed (Figure 1C). Nevertheless, the patient continually presented with tinnitus in the right ear and dizziness. Thus, her hearing function was evaluated.

![Figure 1](image)

**Figure 1**

Pure-tone audiogram at the initial visit showed almost normal hearing threshold on both sides (A). Audiogram 4 years after the initial visit revealed moderate sensorineural hearing loss in the right ear at low and middle frequencies (B). Audiogram after treatment with corticosteroid with partial hearing improvement (C). Audiogram 6 years after the initial visit showed mild hearing loss in the right ear only at low frequencies (D). Audiogram 7 years after the initial visit revealed severe hearing loss in the right ear at all frequencies (E). Audiogram 12 years after the initial visit showed profound sensorineural hearing loss in the right ear (F).
regularly. Results showed moderate hearing loss in the right ear at low frequencies (Figure 1D). Seven years after the initial visit, she complained of worsening hearing loss in the right ear. Audiogram revealed moderate sensorineural hearing loss at all frequencies in the right ear (Figure 1E). She was again treated with corticosteroid. However, there was no hearing improvement. Twelve years after the initial visit, her hearing function deteriorated. Audiogram revealed profound sensorineural hearing loss in the right ear (Figure 1F). Both cervical and ocular vestibular evoked myogenic potential (cVEMP and oVEMP) were not detected upon right ear stimulation (Figure 3A). The video head impulse test (vHIT) showed decreased vestibulo-ocular reflex (VOR) gains in both the anterior and posterior canals on the affected and unaffected sides. Covert catch-up saccades were observed during eye movement elicited by right lateral semicircular canal stimulation. This result indicated decreased right lateral semicircular canal function (Figure 3B). Due to episodes of recurring vertigo and fluctuating hearing loss, endolymphatic hydrops, possibly correlated with MD, was considered as the preliminary diagnosis (12). Thus, delayed 3D-FLAIR MRI was performed to confirm endolymphatic hydrops (10, 11) or identify other conditions. MR cisternography showed a filling defect of fluid intensity in the vestibule of the right ear (Figure 2B asterisk). Gadolinium-enhanced T1-weighted imaging revealed a moderately enhanced region in the right vestibule, which indicated a hypervascular mass in the right vestibule (Figure 2C asterisk). Delayed 3D-FLAIR MRI showed endolymphatic hydrops in the right cochlea (Figure 2D arrows) with a stronger signal intensity in the scala tympani in the basal portion of the cochlea (Figure 2D arrowhead) than in the contralateral ear. The patient wanted to undergo intralabyrinthine tumor resection. Thus, surgery using the translabyrinthine approach was performed (Figure 4). Wide mastoidectomy was performed, followed by transmastoid labyrinthectomy. Then, a pink irregular shaped mass was found to fill the vestibule. After tumor resection, residual tumor was not observed microscopically and endoscopically. An 8-mm mass was completely resected. The whorls of spindle-shaped cells and the palisading structure of cells were consistent with schwannoma. The patient did not present with complications nor vertigo after the surgery. Further, she was followed-up every month, and she underwent clinical vestibular evaluations.

**Discussion**

Herein, we present a case of concurrent endolymphatic hydrops diagnosed via 3D-FLAIR MRI and ILS diagnosed via pathological examination of surgical specimen. To the best of our knowledge, there are only two studies describing endolymphatic hydrops diagnosed via delayed 3D-FLAIR MRI in patients with ILS (7, 13). One possible mechanism underlying endolymphatic hydrops is the presence of a tumor obstructing the ductus reuniens, which connects the cochlear duct and the saccul. Endolymphatic hydrops is also detected via delayed 3D-FLAIR MRI (14) and non-contrast-enhanced 3D-FLAIR MRI (6) in some VS cases. Hence, other than mechanical stenosis of the ductus reuniens, a common mechanism associated with this condition may exist between VSS and ILSs.

ILSs commonly cause unilateral hearing loss, tinnitus, vertigo, and aural fullness, which fairly overlap with MD symptoms. In accordance with this finding, 39% of patients with ILS were previously diagnosed with MD (15). If a patient is diagnosed with MD, the diagnosis is more challenging to reconsider. Our patient was also misdiagnosed with MD. However, she underwent gadolinium-enhanced T1-weighted MRI, which revealed a vestibular tumor. Prior to the initial series of ILSs diagnosed via MRI (16), ILS was diagnosed incidentally during surgery (17, 18), or autopsy (19, 20). Currently, MRI is the gold standard for diagnosing ILSs (1, 2). ILSs are characterized a low signal intensity within the membranous labyrinth, which appears as filling defects, on thin-section T2-weighted images. On post-gadolinium T1-weighted images, ILSs appear as enhanced masses. The
imaging characteristics of our patient were in accordance with those of ILSs. Delayed 3D-FLAIR MRI was initially performed to visualize endolymphatic hydrops in patients with MD (10, 11, 21). A few studies have reported the characteristics of ILSs on delayed 3D-FLAIR MRI (7, 13, 22). The strong enhancement in the ipsilateral cochlear basal on delayed 3D-FLAIR MRI in the current case was in accordance with that of two previous reports on perilymphatic hyperintense areas surrounding the tumor (13, 22). Perilymphatic enhancement on delayed 3D-FLAIR MRI was also detected in patients with intracanalicular or cerebellopontine angle VSs, which might be caused by leakage of gadolinium into the cochlear perilymphatic space via the impaired blood–labyrinth barrier (14). Thus, sensorineural hearing loss in a subset of patients with VSs and ILSs is caused by alterations in blood–labyrinth barrier permeability. In addition, hearing loss was the most common presenting symptom in patients with ILSs regardless of tumor location (2). Homann et al. first detected endolymphatic hydrops via delayed 3D-FLAIR MRI in a patient with ILS (7). In similar studies investigating ILSs via delayed 3D-FLAIR MRI, endolymphatic hydrops was detected in 11.1% (3/27) (13), and 0% (0/3) of patients (22), respectively. However, in studies about ILSs detected via non-contrast-enhanced 3D-FLAIR MRI, endolymphatic hydrops was observed in
Intraoperative findings. After cortical mastoidectomy (A) and labyrinthectomy (B), a pink mass was observed in the right vestibule (arrow) (C). After tumor resection, the intravestibular region was evaluated both microscopically (D) and endoscopically (E). An 8-mm mass was excised (F). (G)

High-power microphotograph showed a nuclear palisading pattern. Scale bar = 100 µm.

**Conclusion**

Combined fluctuating hearing loss and episodic vertigo attacks can be observed in ILS and MD. Therefore, delayed 3D-FLAIR MRI is useful in the diagnosis of concurrent ILSs and endolymphatic hydrops.

**Data availability statement**

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

**Ethics statement**

Ethical review and approval was not required for the study on human participants in accordance with the local legislation and institutional requirements. The patients/participants provided their written informed consent to participate in this study. Written informed consent was obtained from the individual(s) for the publication of any potentially identifiable images or data included in this article.

**Author contributions**

KN conceived the idea of the study and drafted the original manuscript. All authors reviewed the manuscript draft, revised its intellectual content critically and approved the final version of the manuscript for publication.

**Funding**

The study was supported by JSPS KAKENHI Grant Number 22H03239.
Acknowledgments

We thank Tatsuya Aso for pathological examinations.
