Possible Role of Fish as Transport Hosts for *Dracunculus* spp. Larvae

Christopher A. Cleveland, Mark L. Eberhard, Alec T. Thompson, Stephen J. Smith, Hubert Zirimwabagabo, Robert Bringolf, Michael J. Yabsley

To inform *Dracunculus medinensis* (Guinea worm) eradication efforts, we evaluated the role of fish as transport hosts for *Dracunculus* worms. Ferrets fed fish that had ingested infected copepods became infected, highlighting the importance of recommendations to cook fish, bury entrails, and prevent dogs from consuming raw fish and entrails.

The campaign to eradicate *Dracunculus medinensis* infection (Guinea worm disease) has helped 17 of 21 countries interrupt transmission (1). Endemic transmission of Guinea worm disease typically occurred via contamination of drinking water sources, resulting in community disease outbreaks. The absence of outbreaks of Guinea worm disease in Chad, coupled with increasing infections among domestic dogs in the transmission cycle (2–6), led to the hypothesis that transmission was occurring by different means. Previous work on *Dracunculus* and related spirurids indicates that paratenic hosts might be used to facilitate transmission (7,8). Recently, an experimental study showed *D. medinensis* worms could use tadpoles as paratenic hosts, and a naturally infected frog was detected in Chad (9,10). Few data exist on the potential role of fish as paratenic hosts; however, fish are suspected on the basis of epidemiologic data in Chad. At 21 days postinfection, *D. insignis* larvae were examined to determine if they had developed to the infective third stage (i.e., trifid tail). If ≥25% of copepods were infected, they were used for transmission trials. Gravid *D. medinensis* worms were recovered from naturally infected dogs in Chad, and L1s were used to infect cyclopoid copepods collected from N’Djamena.

We then exposed groups of 5 Nile tilapia, fathead minnows, or mosquitofish (*Gambusia affinis*) to groups of 50 copepods (Table). We exposed fish to copepods for 3 hours in the first day of the *D. insignis* trial; on subsequent days, we exposed fish for 2 hours. All copepods provided to fish were consumed during exposures. Individual fish were removed, euthanized by exposure to neutral buffered tricaine methane sulfonate (MS-222) followed by pithing, and dissected. We observed digested copepods and free larvae in the intestine.

We fed the euthanized fish to laboratory-raised ferrets. If fish were not immediately ingested, we mixed the fish carcasses with cat food. Ferrets were fed fish in small batches. For *D. insignis* worms, we conducted exposures using copepods infected with larvae originating from 2 female worms at 2 different times (i.e., 5 fish per day for 3 days in April 2016 and another 5 fish per day for 3 days in July 2016, resulting in exposure to ≥300 copepods) (Table). Because there was only 1 *D. medinensis* worm, fewer *D. medinensis* worm–infected copepods were available. We exposed only 1 species of fish (mosquitofish). A ferret was given 5 fish per day for 6 days for a total of ≥300 copepods. (Table).

We maintained exposed ferrets for 77–134 days, then anesthetized and humanely euthanized them using 30 mg/kg ketamine followed by sodium pentobarbital. We necropsied the ferrets and examined the recovered *Dracunculus* worms to determine sex and whether females were mated or gravid. All animal procedures were reviewed and

Possible Role of Fish as Transport Hosts for Dracunculus Species

Table. Results of ferret exposure trials with 3 different fish species exposed to copepods infected with Dracunculus medinensis or D. insignis worms

| Fish species                  | Dracunculus sp. | No. fish consumed/no. offered* | Total no. copepods† | Days until euthanasia of ferret‡ | Dracunculus infection status of ferret | No. worms recovered and sex§ |
|-------------------------------|-----------------|--------------------------------|---------------------|----------------------------------|---------------------------------------|-----------------------------|
| Mosquitofish (Gambusia affinis) | D. insignis     | 28/30                          | 300                 | 91 and 134                       | –                                     | 0                           |
|                               | D. medinensis   | 30/30                          | 300                 | 77                               | +                                     | 1M/11F                      |
| Tilapia (Oreochromis niloticus)| D. insignis     | 27/30                          | 300                 | 91 and 134                       | +                                     | 6F                          |
| Fathead minnow (Pimephales promelas) | D. insignis | 30/30                          | 300                 | 91 and 118                       | +                                     | 1M                          |

*In groups of 5 fish/day for 6 days.
†>25% of copepods infected.
‡The D. insignis worm–exposed ferrets have 2 entries for days until euthanasia because these animals were exposed to fish at 2 different time points with copepods infected with larvae from 2 different worms.
§All worms were recovered from the subcutaneous tissues of the limbs.
¶Of these 6 female worms, 5 were gravid, indicating a male worm either was missed or had died before necropsy.

Of the 3 ferrets we fed fish that had ingested D. insignis worm–infected copepods, 2 were infected (Table). One ferret was infected with 6 D. insignis females (5 gravid), the other with 1 male worm (Table). The 1 ferret fed fish exposed to D. medinensis worm–infected copepods became infected with 12 worms; female worms were mated but not gravid because of their young age (Table).

Conclusions

The infection of ferrets with Dracunculus spp. worms after consuming fish that had eaten infected copepods demonstrates a novel transmission route. The unprecedented increase in the number of D. medinensis worm infections in dogs in Chad suggests the potential role of aquatic paratenic hosts (2,12). Classically, paratenic hosts become infected and facilitate transmission by bridging a trophic level, maintaining long-term infections, or concentrating larger worm burdens in their tissues (3). We suggest that fish can serve the role of transport hosts because fish did not have disseminated Dracunculus worm infection develop in our initial trials (C.A. Cleveland, unpub. data). Because most cases of Guinea worm disease occur in areas known for intense artisanal fishing and residents’ dependence on fish protein, it is likely that fish and other aquatic animals play a role in transmission.

In 2014, preventive measures such as cooking fish thoroughly, burying fish entrails, and preventing dogs from consuming fish entrails were implemented in Chad. By May 2015, interventions were implemented in >50% of at-risk communities (1). Although limited, surveys for natural infections in fish from Chad’s Chari River have not detected D. medinensis larvae (2; C.A. Cleveland, unpub. data). However, our findings suggest that the proposed intervention strategies involving fish are relevant and should continue. It is unclear what happens in Chad to small fish caught by fishermen; the fish might be consumed whole without cooking or, more likely, are discarded where dogs could consume them. During previous surveys of fish for D. medinensis worms, large numbers of copepods were observed in their gastrointestinal tracts, supporting their potential role as transport hosts (C.A. Cleveland, unpub. data). Despite the interventions implemented in Chad, sporadic dog and human infections are still reported, suggesting a need for continued educational campaigns.

The recent report of a natural amphibian paratenic host, combined with the results of our study, indicates that the transmission of D. medinensis worms is not as simple as once believed (10). Despite the highly successful eradication campaign, 4 countries (South Sudan, Mali, Ethiopia, and Chad) still report endemic D. medinensis worm transmission. All 4 countries now report infections in dogs, so novel intervention and eradication strategies are needed.

Although our study showed that fish can transmit Dracunculus larvae to ferrets, many questions remain. For example, it is likely that different fish species feed on copepods at different rates and have different gastrointestinal tract transit times. This might also explain why individual exposure of mosquitofish to D. medinensis or D. insignis worms led to infection in only the D. medinensis–exposed ferrets; the D. insignis–exposed fish were fed to ferrets an hour later than D. medinensis–exposed fish. It is possible that mosquitofish transit material through the gastrointestinal tract faster than the other species. Alternatively, the ferrets may not have become infected simply because, as previous work has shown, not all ferrets exposed to Dracunculus worms become infected (12). Additional data are especially needed for those fish species that might be caught and ingested by humans or dogs in Guinea worm–endemic countries. Furthermore, 2 fish species retained D. insignis larvae in their tissues for 7–11 days, demonstrating the need for further experimental and field work on the role of fish as paratenic hosts for Dracunculus spp. worms (6).

Acknowledgments

We thank Bob Ratajczak and Matthew Walter for assistance with this project.
The Carter Center funded this research; a full listing of supporters is available at http://www.cartercenter.org/donate/corporate-government-foundation-partners/index.html. Additional support was provided by the wildlife management agencies of the Southeastern Cooperative Wildlife Disease Study member states through the Federal Aid to Wildlife Restoration Act (50 Stat. 917) and by a US Department of the Interior Cooperative Agreement. Additional support for C.A.C. was provided by the ARCS Foundation (Atlanta Chapter) and the Shikar Safari Club, and for A.T. by the National Science Foundation–funded Population Biology of Infectious Diseases REU site at the University of Georgia.

Mr. Cleveland is a PhD student in the Warnell School of Forestry and Natural Resources and the Southeastern Cooperative Wildlife Disease Study at the University of Georgia. He has broad interests in parasite life cycles and transmission dynamics, wildlife management, and the ecology of infectious diseases.
