August 2017

Abstract

This paper examines how the temporary migration of parents for work affects the health of children left behind using longitudinal data from the Indonesian Family Life Survey (IFLS). The evidence suggests that whether parental migration is beneficial or deleterious to child health depends on which parent moved. Migration of the mother seems to have an adverse effect on child height-for-age, reducing height-for-age Z-score by 0.5 standard deviations. This effect is not seen for father’s migration.
Labor Migration in Indonesia and the Health of Children Left Behind

1. Introduction

Economic research on labor migration in the developing world has traditionally focused on the role played by the remittances of overseas migrant labor in the sending country’s economy (for a survey of the empirical literature on remittances, see Adams 2011). In the last decade, more attention has been paid to migration for work and its effects on the socioeconomic outcomes of sending households, thanks in large part to the increased availability of household survey data from developing countries. I contribute to this particular strain of the migration literature by examining how the temporary migration of parents for work affects the health of children left behind, using longitudinal data from the Indonesian Family Life Survey (IFLS). Parental labor migration may be expected to improve children’s nutrition and healthcare through expansion of the household budget constraint from remittances. However, deleterious effects of parental absence could offset these gains. The net effect of parental migration on the health of left-behind children is therefore an empirical question.

Surprisingly little attention has been paid to the relationship between migration and human capital accumulation in Indonesia. One exception is Deb and Seck (2009) who evaluate the effects of migration on an array of socioeconomic outcomes including health of children in Indonesia. This paper differs from theirs in that it focuses on children in households in which only the father or mother, but not the children, migrate, allowing for the isolation of the effects of parental migration without the confounding influence of child migration.
In contrast to many other studies on the relationship between child health and socioeconomic outcomes, I use anthropometric measures of child health rather than subjective health status. Also, the longitudinal design of the IFLS allows for the elimination of all unobserved child- and household-level time-invariant characteristics that are correlated with the explanatory variables, removing a major source of omitted variable bias in the estimated effects of parental migration.

The results suggest that whether parental migration is beneficial or deleterious to child health depends on which parent moved. Migration of the mother seems to have an adverse effect on child height-for-age. This effect is not seen for father’s migration.

From an intrahousehold bargaining perspective, these findings suggest a rejection of the unitary model of the household, whereby a household is assumed to act as a single economic unit, in favor of collective models of intrahousehold allocation (see Vermeulen 2002 for a survey of the collective approach and Vermeulen 2005 for a comparative analysis of the empirical validity of the two competing approaches). In households where mothers are absent due to labor migration, children may receive less care and as a consequence develop poorer health. While speculative, it is possible that the reason for a lack of an adverse effect from father’s migration is that fathers tend to be less directly involved in child rearing.

2. Data and Descriptive Statistics

*Data*
I used data drawn from the 2000 and 2007 waves of the Indonesian Family Life Survey (IFLS). I identify children between the ages of 0 to 7 in 2000 who were reinterviewed in 2007, by which time they were aged 7 to 14. I restrict my attention to children of these ages because they had not reached physical maturity and were still very much subject to key health decisions made for them by their parents.

I use two anthropometric indicators of child health: height-for-age Z-scores (HAZ) and weight-for-age Z-scores (WAZ). In each wave of the IFLS, health workers collected anthropometric data of all household members, including height and weight of children. HAZ are calculated by subtracting each child’s height by the mean for a given age and sex of a reference population and dividing the result by the standard deviation of the reference distribution. WAZ are similarly computed. The reference population is an internationally accepted standard of well-nourished children; I used the 2000 United States Centers for Disease Control growth charts. A HAZ of -1 indicates that, given age and sex, the child’s height is one standard deviation below the mean child in that age/sex group.

Because height and weight represent unobserved nutrients and processes at the cellular level, they are appropriate proxies for child health status (Pelletier 1994). Height-for-age is an adequate proxy of long-term nutritional status (Duggan, Watkins, and Walker 2008). Weight-for-age can reflect both short- and long-term impediments to growth (de Onis 2000). Following Alderman, Hoddinott, and Kinsey (2006), I exclude children whose HAZ or WAZ were less than -6 or greater than 6 because such extreme outliers were likely the result of errors in height, weight or age data. My final dataset consists of 2,841 children interviewed in 2000 and recontacted in 2007.
Migration is coded separately for fathers and mothers. In the interest of brevity let us consider mother’s migration (father’s migration follows analogously). A child interviewed in 2000 is said to have experienced maternal migration if the mother had migrated for the sole purpose of work at least once after the child’s birth up until the time of the interview. The same child recontacted in 2007 is said to have experienced maternal migration if the mother had migrated for work at least once since the 2000 interview. This yields four possible scenarios: 1) mother did not migrate in either period, 2) mother migrated in 2000 but did not in 2007, 3) mother did not migrate in 2000 but did in 2007, and 4) mother migrated in both periods.

Crucial to the analysis is whether there is enough variation in the migration indicator for a relationship between health and migration to be detected. Since variation in the incidence of parental migration comes from scenarios 2 and 3, it is crucial that most of the migration experiences fall under these two scenarios. This was indeed the case. Out of 80 (188) children whose mothers (fathers) migrated in 2000, (77) (181) did not experience maternal (paternal) migration in 2007. In contrast, of the 62 (117) children whose mothers (fathers) migrated in 2007, 59 (110) did not experience maternal (paternal) migration in 2000. No child in my sample had both parents simultaneously migrate for work.

**Descriptive Statistics**

Tables 1a and 1b show the descriptive statistics for the 2,841 children included in the analysis in the year 2000 and 2007 respectively. On the whole, children were less healthy in 2007 than in 2000. To illustrate, average WAZ went from -1.05 in 2000 to -1.11 in 2007. This is consistent with findings from studies on Indonesia; for example, using nationally-representative data from the National
Socioeconomic Survey, Utomo et al. (2011) report an increase in the percentage of children who were underweight between 2000 and 2005, a trend that held across all household expenditure quintiles.

Turning now to cross sectional variation by migration incidence, in the 2000 survey, children with a migrant parent had better health metrics than children whose parents did not migrate. However, the pattern is reversed in 2007; now children with a migrant parent had worse HAZ and WAZ than children whose parents stayed home.

In terms of per capita household expenditures, children with migrant parents were richer in 2000 but poorer in 2007. In 2000, migrant parents were more educated than non-migrant parents, but the opposite was true in 2007. Lastly and unsurprisingly, in both years children with migrant parents were more likely to live in rural areas.

These descriptive statistics reveal significant cross sectional differences between children based on the migrant status of their parents. How these differences would manifest themselves over time is a question that can be answered using panel data analysis. In the next section I turn to controlling for the observed characteristics discussed here to isolate the influence of parental migration in the determination of child health.

3. Empirical Strategy

Theoretical Motivation
My empirical strategy is grounded in the assumption of a static health production function for an individual: \( H = H(N; T(A, B, D), u) \), where \( H \) represents a vector of measured health outcomes.\(^6\) They depend on a vector of health inputs, \( N \). Health inputs are under the control of the individual and include, for example, use of health care facilities, nutrient intake, and time used for the production of health. The technology, \( T \), or shape of the underlying health production function varies over the life course. It is determined by demographic characteristics, \( A \), such as age and sex; aspects of family background that affect health, \( B \), such as parental health and genetic endowment; and environmental factors, \( D \).

In the case of child health production, parents can be assumed to play a role in the determination of \( N \). Parental migration can affect \( N \) in a several ways. Migration necessarily involves a prolonged or temporary absence of the parent in a child’s life, which could have deleterious consequences on the quality of \( N \). On the other hand, if migration improves household income, \( N \) could be positively impacted. The net effect of parental migration has to be ascertained empirically.

**Empirical Specification**

I estimate the following regression equation for child \( i \) in household \( b \) at time \( t \):

\[
\text{Health}_{ibt} = \alpha \text{MigrantFather}_{ibt} + \beta \text{MigrantMother}_{ibt} + X_{ibt} \delta + \mu_i + \pi_b + \text{error}_{ibt}
\]

I run two separate child-level regressions, one for HAZ as the dependent variable and another for WAZ. \( \text{MigrantFather} \) is a dummy variable indicating whether the father migrated for work up until time \( t \). \( \text{MigrantMother} \) is analogous for mothers. \( X \) is a set of child observable characteristics that
could also be correlated with child health status, namely age, parental education level, log monthly per capita household expenditures, and a dummy for whether the child resides in an urban area. I also include a dummy for 2007 to control for unobserved secular time effects that are potentially correlated with the migration decision. $\mu_i$ and $\pi_h$ are child and household fixed effects, respectively. Their inclusion removes any unobserved confounding characteristics of the child and household that do not change over time.

Although the estimates of the relationship between parental migration and child health are robust to time-invariant unobserved characteristics, the data do not allow me to establish the direction of causality in the relationship. For instance, it could be that a parent migrated for better economic opportunity in response to a child’s poor health. Therefore, the estimates in this paper should not be interpreted as causal.

4. Results

Estimates from the health regressions are presented in Table 3. As shown in column 1, having a mother who migrated for work is associated with a half standard deviation decrease in HAZ, statistically significant at the 5 per cent level. However, migration of the father does not exhibit this negative effect on child health; if anything, children with migrant fathers have better HAZ, although the relationship is statistically insignificant.

Child WAZ is not statistically significantly correlated with either maternal or paternal migration. The absence of a significant relationship between parents’ migration and child weight could be explained
by the composite nature of weight-for-age; it is influenced by the child’s height and weight, which makes interpretation complex (Baker, Baker, and Davis 2007).

All estimates are robust to a logarithmic specification of age to account for potential nonlinearities in the relationship between the health scores and age, and are also robust to heteroskedasticity within households.

As an interesting aside, the data reveal no significant difference in the health indicators between girls and boys (Tables 2a and 2b), consistent with previous research showing no evidence of son preference in Indonesia (Kevane and Levine 2003; Levine and Ames 2003; Mani 2007). The one exception is WAZ in 2007, but rather than son preference, the evidence suggests that girls in that year were healthier than boys.

**Selective Attrition**

Attrition bias is always a potential concern with panel data. If less healthy children were more likely to drop out of the IFLS, the estimated parental migration effects would be attenuated. Out of 2,924 children aged 0-7 from the 2000 survey, 83 dropped out in the 2007 wave. This high recontact rate (97%) alleviates much of the concern about selective attrition. Nonetheless, I test for the presence of selective attrition on observables following the methodology of Fitzgerald, Gottschalk, and Moffit (1998). I regress 2007 attrition status on the child health indicators plus all other explanatory variables from 2000: if the lagged values of health do not significantly affect attrition, it would further strengthen the case against attrition bias being a concern. As shown in Table 4, neither HAZ nor WAZ is a significant predictor of the likelihood of a child to attrite.
5. Conclusion

In this paper, I present evidence that migration of the mother for work may have a net negative impact on height-for-age, a measure of health for children. On average, having a mother who migrated for work at least once between 2000 and 2007 pushed children farther below the average height for their age and sex by half a standard deviation. Coupled with the fact that the average Indonesian child is underweight relative to the global mean, this is a cause for concern. I find no evidence of such an effect on height-for-age from migration of the father. In conclusion, this study reveals the possibility that leaving a child behind for economic opportunity can have a net negative effect on the child’s health if it is the mother who makes the move.
### Figures and Tables

Standard errors are robust to clustering at the household level.
Regressions include child and household fixed effects.
The omitted category for years of schooling is 0-1 years.
Household expenditure is the sum of expenses on food, nonfood items (durable and non-durable), and education, as reported by a female respondent, either the spouse of the household head or another person most knowledgeable about household affairs.
Table 4. Selective attrition

Explanatory variables are from the 2000 wave of the IFLS.
1 Mexico in particular has received much attention; see Antman (2012b), Antman (2012a), Antman (2011a), Antman (2011b), Antman (2010), Hildebrandt and McKenzie (2005).
2 A number of recent works in economics has found adverse effects of parental absence on various indicators of child wellbeing such as cognition and school attendance; see for example Zhang et al. (2014) and Pörtner (2016).
3 Examples of papers in development studies that employ anthropometric measures of health are Domingues & Barre (2013) for Mozambique and Brainerd (2010) for the Soviet Union.
4 The CDC growth charts can be accessed at https://www.cdc.gov/growthcharts/cdc_charts.htm
5 In the development economics literature, consumption is widely considered superior to income as a measure of individual wellbeing in developing countries. Deaton (1997) explains that consumption is a better measure of lifetime welfare than is current income on theoretical (i.e. the permanent income hypothesis) and practical grounds (it is more reliably measurable).
6 See the Strauss and Thomas (2007) Handbook of Development Economics chapter for a treatment.
