Abstract
Introduction: Vitamin D receptor (VDR) plays a key role in the metabolism and differentiation of keratinocytes; thus, associations between VDR polymorphisms and Psoriasis vulgaris (PsV) onset have been sought for many years. The results of these studies have not been conclusive. To date there are no studies in Mexico regarding the association between these polymorphisms and the clinical manifestations of PsV.

Objective: The aim of this study was to determine the association between polymorphisms in the VDR gene (FokI, BsmI, ApaI and TaqI) and the clinical manifestations of PsV in a group of Mexican patients.

Methods: The study group consisted of 52 patients from north (NPsV n=24) and western (OPsV n=28) regions of the country diagnosed with PsV. This group of patients were compared with healthy donors from the western (POc n=50) and northern (PN n=50) regions. RFLPs were identified to determine allelic and genotypic frequencies for all the groups. Hardy-Weinberg equilibrium (HWE) as well as haplotype distributions were estimated. Statistical tests were X² and Fisher’s exact test. Haplotype distribution was carried out with SNPassoc software.

Results: There was no significant difference when the genotypic frequencies between patients and controls are compared; however, there is an association between the TT(ff) genotype of FokI polymorphism and clinical manifestations. The most frequently observed haplotypes of polymorphisms (FokI, BsmI, ApaI and TaqI) have significantly different distributions (p=0.0001) between patients with PsV and controls.

Conclusions: Our results show that the polymorphisms FokI, ApaI, BsmI and TaqI in the VDR gene are not associated with the risk of presenting PsV in Mexican population, but the TT(ff) genotype of the FokI polymorphism is significantly more common in patients with late onset of PsV (after age 40) and those without nail affection. More studies including a greater number of samples and other polymorphisms must be analyzed.

Keywords: Psoriasis vulgaris; Vitamin D receptor; Polymorphisms; Mexican patients

Introduction
Psoriasis vulgaris (PsV) is a multifactorial disease characterized by well-circumscribed erythematous plaques, constant skin flaking and intense pruritus, that affects specific skin areas. PsV worldwide prevalence ranges from 0.4 to 4.8% and in Mexico 2% of the population presents this disease. It is well known that Vitamin D Receptor (VDR) plays a key role in both the metabolism and differentiation of keratinocytes [1]. The gene encoding the VDR is located on chromosome 12cen-q12, contains 11 exons and spans approximately 75 kb of genomic DNA. Several polymorphisms have been identified in the gene including the Fok I polymorphism located in exon 2 at the 5’ coding region of the gene [2]. For this reason, researchers have attempted to establish an association between VDR gene polymorphisms and the onset, presence and response of treatment of psoriasis vulgaris. The aim of this study was to determine the association between four polymorphisms on the VDR gen (FokI, BsmI, ApaI and TaqI) and the clinical manifestations of PsV in a sample of Mexican patients.

Materials and Methods
Samples
Peripheral blood from a total of 52 patients (aged 5-68 years) and 100 healthy donors was taken after obtaining informed consent. The diagnosis was based on the clinical history, classic features, and a positive Auspitz’s sign. The Psoriasis Area Severity Index (PASI) was also assessed. At least one first-degree relative diagnosed with PsV was reported by 48% of the patients.

Analysis of polymorphisms
Total DNA was obtained from blood by the Gustincich method [3]. Three sets of primers previously described were used to amplify exons 4 and 11, and intron 10 of the VDR gene [4]. Amplified fragments were analyzed by RFLP using the enzymes FokI (rs2228570), TaqI (rs731236), ApaI (rs7975232) and BsmI (rs1544410); the latter SNP was confirmed with the enzyme HhaI and by direct sequencing (sequencer model ABIPRISM310, Applied Biosystems, Foster City, CA). All PCRs were performed according to the manufacturer’s protocol (New England Biolab, Ipswich, MA) and the products were visualized on 1% agarose gels stained with bromide after electrophoresis.

Statistical analysis
The genotype and allele frequencies were analyzed using the Chi square test (X²); in addition, the relative risk for disease and clinical variables was established. Models of dominant, co-dominant or...
Results

Of the total of patients (n=52) with PsV, 78% (n=38) corresponded to early onset PsV; 65% (n=39) did not have nail involvement and 48% of patients (n=25) reported at least one first-degree relative diagnosed with psoriasis.

The PASI score obtained by the study universe was mild in 81%, moderate in 13%, and severe in 6% with a mean of 5.04, range 0.3 to 32. The polymorphisms BsmI (p=0.042) and Apal (p=0.011) did not show HWE in the reference population. By analyzing the distribution of allelic and genotypic frequencies regarding the clinical variables mentioned above, it is observed that under the dominant model, the TT(ff) genotype was significantly more frequent in patients with late onset PsV (40 or older) (p=0.033) and in patients without nail involvement (p=0.015). The TT (aa) genotype was significantly more frequent under the recessive model, in patients with a negative family history (p=0.049) (Table 1). According to the haplotype analysis in the SNPstats platform, we observed significant differences in the most common haplotype in the reference population HplVDR1 (FbT, 21.1%) compared to patients with PsV HplVDR2 (FbAT, 24.1%) (p=0.001). Considering only 3 of the polymorphisms located just before the 3’ region of the VDR gene (BsmI, Apal and TaqI), we found that haplotypes significantly different between healthy donors and PsV patients were HbpAT1 (bAT 32.4%) vs. HpBAt2 (bAT, 49.7%), respectively (p<0.001). Although we found no association of any haplotype in particular with the presence of PsV, we did find a significant difference (p<0.001) between the distribution of the haplotypes composed of the recessive alleles Fokl and Apal (f and a) in patients with PsV vs. the reference population (Table 2). This is the first report of a possible association of the ff genotype in VDR gen (rs2228570) with the clinical variables, late age of onset, and no nail involvement, and also the first time a protective effect of VDR gen (rs2228570) with the clinical variables, late age of onset, and a) in patients with PsV vs. the reference population (Table 2).

Haplotype frequencies were performed using the expectation-maximization algorithm. A p value <0.05 was considered significant. The platform used for statistical analysis was SNPstats [6].

Finally, vitamin-D is a member of the steroid receptor family and mediates the effects of the active metabolite 1, 25(OH)2 vit D3 by regulating transcription of a number of different cellular genes. The action of vitamin D is mediated through its binding to nuclear receptor (VDR) [12]. The Fokl Vitamin D Receptor (VDR) polymorphism results in different translation initiation sites on VDR. In the VDRf variant, initiation of translation occurs at the first ATG site, giving rise to a full length VDR protein of 427 amino acids. Conversely, in the VDRff variant, translation begins at the second ATG site, resulting in a truncated protein with three less amino acids [13]. This study found an association in Fokl polymorphism of VDR gene and two major clinical variables, suggesting that the genotype [Tf/Tf] may be a protective factor for nail involvement and age of onset in Mexican patients with PsV.
