ABSTRACT
We present an analysis of a high-resolution ($R \approx 40\,000$) infrared spectrum of the RS Oph secondary around the first overtone CO bands, obtained in 2008 May on the Gemini-South 8 m telescope. The $^{12}$CO and $^{13}$CO bands are well resolved, and we compute synthetic spectra to determine the $^{12}$C/$^{13}$C ratio. We find $^{12}$C/$^{13}$C $\simeq 16 \pm 3$, consistent with the interpretation of the secondary as a red giant which has evolved beyond the first dredge-up phase of evolution.

Key words: stars: abundances – binaries: symbiotic – stars: individual: RS Oph – novae, cataclysmic variables.

1 INTRODUCTION
RS Ophiuchi is a recurrent nova (RN), an interacting binary system in which multiple nova outbursts have been observed. It has undergone eight known or suspected outbursts since 1898 (Anupama 2008), the most recent one occurring on 2006 February 12.83; we take this date as $t = 0$.

RS Oph consists of a white dwarf (WD) primary close to the Chandrasekhar limit, accreting material from a red giant (RG) secondary with a substantial wind (Fekel et al. 2000). The RN eruption is explained in terms of a thermonuclear runaway (e.g. Anupama 2008; Starrfield 2008) following the accretion of sufficient mass by the WD to trigger ignition. If the mass accreted by the WD is greater than the mass ejected then the mass of the WD must increase, so the ratio of mass accreted to mass ejected will determine whether or not RS Oph is a potential Type Ia supernova (SN) progenitor (Panagia et al. 2006; Sokoloski et al. 2006). Drake et al. (2009), modelling the X-ray absorption spectra observed with Chandra after the 2006 February outburst, argue that the mass ejected from the WD in the RS Oph system is $\sim 5 \times 10^{-6} M_\odot$. However, Worters et al. (2007) argue that the RG in the RS Oph system loses $\sim 10^{-8} M_\odot$ yr$^{-1}$, while the WD accretes at rates of $10^{-10} \lesssim M_{\text{acc}} \lesssim 10^{-9} M_\odot$ yr$^{-1}$, suggesting that $\sim 2 \times 10^{-9} M_\odot$ of material is accreted during the inter-outburst interval. Intercomparison of mass-loss rates from the RG to the amount of material ejected by the WD can determine whether symbiotic systems are candidate SN progenitors (Panagia et al. 2006); however, mass-loss rates are of course difficult to pin down observationally.

Pavlenko et al. (2008) showed that the secondary in RS Oph is an RG with $T_{\text{eff}} = 4100 \pm 100$ K and solar metallicity, but with a deficit of carbon and an overabundance of nitrogen with respect to solar. Rushton et al. (2010) have modelled the spectral energy distribution (SED) of RS Oph in the near-IR (1–5 $\mu$m) and found that $T_{\text{eff}}$ is essentially constant over the period of 2006 August–2008 July. Nitrogen overabundance, and carbon underabundance, is typical of ‘normal’ RGs due to the conversion of C to N in the CN cycle of hydrogen burning and the subsequent dredge-up of the products on the red giant branch (RGB; Smith & Lambert 1985, 1986; Smiljanic et al. 2009). Furthermore, the material accreting on to the WD from the M giant secondary in the RS Oph system is likely N-enhanced (see fig. 14 of Ness et al. 2009). Interestingly, the C and N abundances for RS Oph found by Pavlenko et al. (2008) are similar to those in the RG-WD binary (star 69) in the open cluster IC 4756 (Smiljanic et al. 2009).

The $^{12}$C/$^{13}$C isotopic ratio is of key importance for understanding the evolutionary status of RGs. At the beginning of the RGB, the deepening convective envelope brings nuclear-processed matter from the core up to the surface of the star. As a result of the first dredge-up, the carbon isotopic ratio decreases up to a factor of $\sim 20$, depending on stellar mass and metallicity (Charbonnel 1994), and standard models of stellar evolution predict no change in $^{12}$C/$^{13}$C thereafter. However, observations of evolved RGs with a progenitor mass of $\lesssim 2 M_\odot$ indicate that the $^{12}$C/$^{13}$C ratio continues to decrease after the completion of the first dredge-up event (Smith, Hinkle & Cunha 2002; Tautvaisienè et al. 2005; Smiljanic et al. 2009, and references therein). Most probably further mixing, or some non-standard mixing, mechanisms work in low-mass stars as they are ascending the RGB (Charbonnel 1994, 1995). Anticorrelation of the carbon and nitrogen abundances, as is seen in RS...
Oph (Pavlenko et al. 2008), is well known for a variety of RGs with a range of metallicities (Smith, Briley & Harbeck 2005, and references therein).

The $^{12}$C/$^{13}$C ratio is also of fundamental importance in understanding the nature of the secondary of RNe, as it is a reflection of the relative importance of $^{12}$C, $^{13}$C processing and dredge-up. Following the 1985 eruption, Evans et al. (1988) estimated a $^{12}$C/$^{13}$C ratio of $\sim$10 for the RG in RS Oph on the basis of a low-resolution infrared (IR) spectrum, while Scott et al. (1994) found that the strength of the first overtone CO bands declined by a factor of $\sim$10 over the first 7 yr after the eruption (see also Harrison, Johnson & Spyromilio 1993).

In this paper, we discuss Phoenix echelle observations of the first overtone vibration–rotation features of CO, obtained in 2008 May, some 831 d after the 2006 outburst, to determine the $^{12}$C/$^{13}$C ratio in the atmosphere of the RS Oph secondary.

2 OBSERVATIONS AND REDUCTION

High-resolution $H\ K\ M$-band spectral observations of RS Oph were carried out on the Gemini-South 8 m telescope using the Phoenix spectrograph (Hinkle et al. 2003) during queue observing runs on the nights of 2008 May 23 and 24 UT (days 830.7, 831.7 from the 2006 eruption), as part of our Gemini programme GS-2008A-Q47. Defining the zero orbital phase as the maximum RG radial velocity, the observations discussed here were obtained at binary phase 0.78, when approximately 88 per cent (assuming the adopted inclination of $\sim$40°; Fekel et al. 2000; Ribeiro et al. 2009) of the visible photosphere of the RG was illuminated by the WD.

Observations of RS Oph (as well as the telluric standard HR 6378 = $\eta$ Oph[A2V, $V = 2.43$] at a comparable airmass) were obtained by nodding the target at multiple positions along the long axis of the 14 $\times$ 0.34 arcsec$^2$ slit (e.g. Smith et al. 2002). Observations of the telluric standard were conducted immediately before and after the observations of RS Oph, with flats and darks being obtained at the conclusion of each observational sequence comprising a given grating and order-sorting filter combination. With our instrument configuration, the Phoenix spectrograph produces single-order echelle spectra with a resolution of $R = \lambda / \Delta \lambda \approx 40\ 000$ (corresponding to a resolution element of $\sim$4 pixels). Individual spectra were reduced and combined using standard IR data reduction techniques as well as those unique to Phoenix (Hinkle et al. 2003; Hinkle, Brittain & Lambert, 2007). Table 1 summarizes the observational data discussed herein.

The echelle spectra discussed here covered the 2.32–2.33 and 2.36–2.38 $\mu$m spectral regions; we refer to these as spectra ‘B’ and ‘R’, respectively. Both spectra are affected by curvature of the echelle orders. We reduce the intensities of spectral features in most regions using the theoretical spectrum continuum as reference points. The effects are more pronounced in the ‘B’ spectral region (see Fig. 1) and we work with the spectra in terms of residual fluxes. We cannot determine the real continuum due to noise at the minimum fluxes. Therefore, we carried out fits to the observed spectrum using different levels of the continuum. We refer to these

| Date (2008 UT) | Filter | $\lambda$ range ($\mu$m) | Exposure (s) | Airmass |
|----------------|--------|-------------------------|--------------|--------|
| May 23         | K4308  | 2.32–2.33               | 1650         | 1.18   |

Figure 1. Theoretical spectra of different species in our spectral region, convolved by a Gaussian with a half-width of $10^{-8}$ $\mu$m. Synthetic spectra were computed for a model atmosphere having $T_{\text{eff}} = 4000$, $\log g = 0$, $[\text{Fe}/\text{H}] = 0.0$ for (a) $^{12}$CO, (b) $^{13}$CO and (c) the VALD line lists. Observed spectra (d, e, f) in both spectral regions are also shown. The ‘B’ spectrum is shown before (d) and after (e) echelle order correction. The flux scale is arbitrary, and all spectra are shifted vertically to simplify the plot.

values of the virtual continuum as pseudo-continuum. The results of the fits depend on the pseudo-continuum level, as discussed in Section 4.

3 ANALYSIS PROCEDURE

3.1 Spectral synthesis

We have used the technique of synthetic spectra to carry out our analysis of the IR spectrum of RS Oph; details may be found in Pavlenko et al. (2004, 2008). We computed the spectra within the classical framework, assuming local thermodynamic equilibrium (LTE), plane-parallel media, and no sinks or sources of energy in the atmosphere; the transfer of energy is provided by the radiation field and by convection. Strictly speaking, these assumptions are not completely valid in the atmosphere of the RG in RS Oph; however, this approach allows us to describe the IR SED of RS Oph over a wide range of wavelengths, and we consider that none of our assumptions is of crucial importance in the spectrum formation processes.

In the most general case, any determination of abundance depends on many adopted parameters: $T_{\text{eff}}$, $\log g$ and $V_t$, and the abundance of other elements. In this paper, we solve a restricted task using fits to the two observed narrow spectral regions in the infrared. Therefore, to reduce the number of fitted parameters in the minimization procedure, we adopt for the secondary atmosphere $T_{\text{eff}} = 4200$ K and $\log g = 0.0$, obtained from fitting near-IR low-resolution spectra (Pavlenko et al. 2008). We then fix the abundances of carbon and nitrogen at $\log N(\text{C}) = -4.2$ and $\log N(\text{N}) = -3.2$, respectively, on the scale $\Sigma N_i = 1$, as also determined from fitting the low-resolution spectra by Pavlenko et al. (2008); other abundances are taken to be solar.

We assume that the observed spectra are broadened by macroturbulence in the RG atmosphere and by instrumental broadening; both are implemented in the modelling by smoothing the computed spectra with a Gaussian of a full width at half-maximum (FWHM) of $\sim$1.9 $\AA$, which is a reasonable approach for fitting stellar spectra. In fact, the appropriate values of FWHM were determined by
our minimization procedure fitting to the observed spectrum (see Pavlenko et al. 2004).

To determine the isotopic ratio $^{12}\text{C}/^{13}\text{C}$, we follow conventional procedures. Namely, we define $x$ as the fraction of $^{12}\text{CO}$ molecules, i.e., $x = N(^{12}\text{CO})/(N(^{12}\text{CO}) + N(^{13}\text{CO}))$, where $N(M)$ is the number density of the molecule $M$. Then, the fraction of $^{13}\text{CO}$ molecules is clearly $N(^{13}\text{CO})/N(^{12}\text{CO}) + N(^{13}\text{CO})) = 1 - x$. In this approach we operate with two parameters, i.e., the abundance of carbon $N(C)$ (as specified above) and the isotopic ratio $^{12}\text{C}/^{13}\text{C} = N(^{12}\text{CO})/N(^{12}\text{CO}) = x/(1 - x)$. Then all synthetic spectra are computed for the $^{12}\text{CO}$ and $^{13}\text{CO}$ molecular densities, determined by taking into account the input isotopic ratio $^{12}\text{C}/^{13}\text{C}$.

The ‘B’ spectrum contains no $^{13}\text{CO}$ lines, only $^{12}\text{CO}$ (Fig. 1). Again, we note that, in the most general case, the intensities of these lines depend on both $\log N(C)$ and $V_t$. We used this spectrum to determine the microturbulent velocity $V_t$ for the adopted value of $\log N(C)$ in the atmosphere of the RG. The ‘R’ spectrum contains both $^{12}\text{CO}$ and $^{13}\text{CO}$ lines; we used this spectrum to determine the carbon isotopic ratio $^{12}\text{C}/^{13}\text{C}$.

A set of continuum opacity sources from ATLAS9 (Kurucz 1993) with some additional amendments (Pavlenko et al. 2004) was used in our modelling, as well as the VALD atomic line list (Kupka et al. 1999) and line lists of $^{12}\text{CO}$ and $^{13}\text{CO}$ from Goorvitch (1994). The quality of the Goorvitch data is demonstrated by the fact that Pavlenko (2008) recently fitted theoretical spectra to a high signal-to-noise ratio 2.3 mm spectrum of Arcturus, giving excellent fits to the CO bands. Water vapour lines were not included because numerical experiments with the Barber et al. (2006) H2O line list showed that their contribution to the total opacity in the wavelength range under consideration is negligible. We adopt the Voigt profile $H(a, v)$ for the shape of each line; here $a = (\gamma_2 + \gamma_4 + \gamma_6)/ (4 \times \pi \times \Delta v_2)$, $v = \Delta v/\Delta v_2$, (see Gray 2005, for details). Damping constants $\gamma_2$, $\gamma_4$ and $\gamma_6$ are, respectively, due to the natural, van der Waals and Stark broadening of atomic and molecular lines, computed using data from various data bases (Kurucz 1993; Kupka et al., 1999), or the approximation of Unsöld (1955). Natural and van der Waals broadening dominate in the case of RS Oph, due to the low pressure and electron density in the RG atmosphere. We note the following.

(i) Molecular lines are less sensitive to pressure broadening, because they form in low density regions of the RG atmosphere.

(ii) Thermal velocities of the CO molecule are lower than those of C and O atoms due to its higher mass. For the CO molecular lines, broadening by microturbulence dominates, especially in the low temperature regime; we determine the microturbulence velocity in Section 4.

(iii) The wings of the molecular lines are blended in the spectra of the RG.

The contributions of the various molecular and atomic species to the total opacity in the 2.28–2.39 mm spectral region are shown in Fig. 1, from which we see that absorption by CO dominates.

Full details of our procedure of fitting theoretical fluxes to observed SEDs may be found in Pavlenko et al. (2004).

3.2 The effect of circumstellar dust

Dust is present in the RS Oph system (Evans et al. 2007; van Loon 2008; Woodward et al. 2008), emitting primarily at $\lambda \gtrsim 10 \mu m$. However Rushton et al. (2010) have shown that there is also evidence for dust emission at shorter ($\gtrsim 5 \mu m$) wavelengths and that emission by the dust envelope may be variable.

The properties of the dust shell around RS Oph have been discussed by Evans et al. (2007), van Loon (2008) and Woodward et al. (2008). Pavlenko et al. (2008) and Rushton et al. (2010) have shown that the 2 mm spectral region of RS Oph is not affected by emission from the hot ($\sim 500$–$600$ K) dust known to currently envelop RS Oph, which is likely a permanent feature of the system. As this dust emission becomes prominent longwards of 3 mm, we are justified in carrying out our analysis for the dust-free case.

4 RESULTS

In principle, the $^{12}\text{C}/^{13}\text{C}$ isotopic ratio can be determined from any pair of the unblended lines of $^{12}\text{CO}$ and $^{13}\text{CO}$. However, in our spectra these lines are blended and we are unable to distinguish the $^{12}\text{CO}$ lines from the weaker $^{13}\text{CO}$ lines at our spectral resolution. Absorption of both species forms common blends in the observed and modelled spectra. Only the band heads of the CO system can be clearly identified in the spectrum, formed by saturated lines which have rather weak dependence on the CO abundances. Moreover, they form in the outermost layers of RG atmosphere which cannot be modelled in the framework of the classical approach. Non-saturated lines, especially those of intermediate strength, are a better choice for the abundance determination; however, they are sensitive to the microturbulent velocity.

We determined the microturbulent velocity from the fits to the ‘B’ spectrum (2.32–2.33 mm), which is formed completely by absorption of $^{12}\text{CO}$ lines. The spectrum shows a strong dependence on $V_t$ (Fig. 2). The minimization procedure for the parameter $S$ (see below) gives a definite value for the microturbulent velocity of $V_t = 3.0 \pm 0.5$ km s$^{-1}$ (close to the value assumed in Pavlenko et al. 2008). In what follows, we compute spectra with $V_t = 3$ km s$^{-1}$ to fit the ‘R’ spectrum and determine the $^{12}\text{C}/^{13}\text{C}$ ratio in RS Oph.

To determine the $^{12}\text{C}/^{13}\text{C}$ ratio, we fitted computed spectra to the observed ‘R’ spectrum. We note the following.

(i) In the computed spectrum, we see flux maxima which can be treated as continuum. At these wavelengths, the contribution of absorption in the line wings is negligible.

(ii) The ‘R’ spectrum is affected by noise, as already noted. We attribute these features to noise because their widths do not match the spectral resolution.

(iii) In order to study the effect the continuum level has on our results, we varied the level of continuum in the observed spectrum; for each individual level, we found values of $^{12}\text{C}/^{13}\text{C}$.

The continuum level in the observed spectrum was adopted at the following points: $d = r_c/r_{\text{max}} = 0.88, 0.90, 0.92, 0.94, 0.96, 0.98, 1.00$, the value $d = 1.00$ corresponding to the level of the formal maximum flux $F_{\text{max}}$ in the observed spectrum. Here, $r_c = F_c/F_{\text{c}}$ is the residual flux. Adopted levels of continuum $F_c$ in the observed spectrum are clearly seen in Fig. 3.

In Fig. 3 we show the dependence of the synthetic spectra on the $^{12}\text{C}/^{13}\text{C}$ ratio for $V_t = 3$ km s$^{-1}$, while in Fig. 4 we show the dependence of the best-fitting parameter $S = \sum (1 - r_{\text{syn}}/r_{\text{obs}})^2$ on the $^{12}\text{C}/^{13}\text{C}$ ratio for different levels of continuum $d$ in the observed spectrum.

Using our fitting procedure, we found a clear dependence of the minimum $S$ value and of the $^{12}\text{C}/^{13}\text{C}$ ratio on the level of pseudo-continuum. The formal best fit ($^{12}\text{C}/^{13}\text{C} = 24 \pm 3$) is obtained with $d = 0.88$. However, visual comparison with the observed spectrum shows that the level of the theoretical pseudo-continuum is too low in this case. As we see from Fig. 3, the best fits with $^{12}\text{C}/^{13}\text{C} = 13–19$ well reproduce the profiles of the CO lines, dependent on the chosen
First overtone CO bands in RS Oph spectrum

Figure 2. Left: dependence of S on the adopted $V_t$. Right: fits of spectra computed with different $V_t$ to the observed ‘B’ spectrum of RS Oph. The model atmosphere has $T_{\text{eff}} = 4200$ K, $\log g = 0.0$ (Rushton et al. 2010).

Figure 3. Spectral fits computed with different $^{12}\text{C}/^{13}\text{C}$ to the observed ‘R’ spectrum of RS Oph. Pseudo-continuum positions at $r_\nu = 0.90, 0.92, 0.94$ are shown; the colour key is as per the $^{12}\text{C}/^{13}\text{C}$ ratio. Spectra of $^{12}\text{CO}$ and $^{13}\text{CO}$ molecules taken from Fig. 1 are shown on the top; they are shifted on the y-axis to simplify the plot.

pseudo-continuum and noting that the values of S are high due to the presence of unidentified spectral features. Most likely, these features form beyond the atmosphere of the RG (see below). Therefore, using goodness of fit as judged ‘by eye’ to complement our minimization procedure, we choose the value $^{12}\text{C}/^{13}\text{C} = 16 \pm 3$ from the best fits of synthetic spectra and pseudo-continuum, computed for our assumed $T_{\text{eff}}, \log g$ and abundances to the observed ‘R’ spectrum.

Interpretation of the ‘R’ spectrum is not as straightforward as that of the ‘B’ spectrum in that the noise level increases to longer wavelengths. Indeed, the noise level in the ‘R’ spectral region is...
Figure 4. Dependence of $S$ on the adopted $^{12}\text{C}/^{13}\text{C}$. The model atmosphere has $T_{\text{eff}} = 4200\,\text{K}$, $\log g = 0.0$ (Pavlenko et al. 2008), $V_t = 3\,\text{km}\,\text{s}^{-1}$. Curves on the plot are labelled by a pair of numbers $d/xxx$, where $d$ and $xxx$ are the adopted levels of continuum and the $^{12}\text{C}/^{13}\text{C}$ ratio found at the min $S$, respectively.

generally higher than that in the ‘B’, likely due to a decrease in atmospheric transmission longwards of about $2.4\,\mu\text{m}$. Also, absorption features are seen in the ‘R’ spectrum which cannot be identified with CO; most likely, these are a consequence of the data reduction procedure, where time-variable telluric features are not adequately removed from the spectra. Indeed comparison of the computed and ‘R’ spectra reveals the presence of some unidentified features in the observed spectrum, although some of these may be artefacts produced by the removal of the telluric spectrum. This is not true for the ‘B’ spectrum. The $^{13}\text{CO}$ lines, which are our main interest, are clearly seen in the ‘R’ spectral region; none of the unidentified features in the ‘R’ spectrum region is identified with $^{12}\text{CO}$, $^{13}\text{CO}$ lines and so their presence does not affect our conclusions.

5 DISCUSSION

We have determined the $^{12}\text{C}/^{13}\text{C}$ isotopic ratio in the atmosphere of the RS Oph secondary for orbital phase 0.78 – when approximately $88$ per cent of the visible RG surface was irradiated by ultraviolet radiation emitted by the WD – to be $16 \pm 3$. This is consistent with that expected after the first dredge-up (Charbonnel 1994) and suggests that the RG in RS Oph has undergone the first dredge-up and has evolved beyond this evolutionary stage.

In spectra shown by Rushton et al. (2010), numerous emission lines are visible in the spectral regions around $1.0–1.8\,\mu\text{m}$. These form in material ejected in the 2006 eruption or in the shocked or ionized RG wind, in each case well away from the photosphere of the secondary. Moreover, in optical spectra we see pronounced effects of irradiation.

By the time of our observations in 2008, RS Oph had essentially returned to quiescence, and we do not expect irradiation to have a strong impact on the spectrum in the $2\,\mu\text{m}$ region. Furthermore, the molecular bands we observe in the IR are formed deep in the atmosphere of the RG. However, as evidenced by the strong emission-line spectrum (Rushton et al. 2010), a hot circumstellar envelope exists and may affect the spectral details, even in the IR. As we see in Fig. 2, the fits to the saturated $^{12}\text{CO} \, v = 3 \rightarrow 1$ band at $3.23\,\mu\text{m}$ are imperfect in that the observed molecular lines are shallower than the theoretical bands, which are more saturated. This poorer fit could, in part, be due to the uncertainty in the continuum level in the ‘R’ spectrum (Fig. 3). On the other hand, weakening of the CO can be interpreted as a consequence of higher temperatures in the regions where it is formed so that the structure of the outer layers of the atmosphere of the RG may differ from the classical model atmosphere assumed here.

We note that Rushton et al. (2010) report weaker CO first overtone absorption in their 2007 observations than in their 2006 and 2008 observations. Similar changes were observed following the 1985 outburst by Scott et al. (1994), who attributed this behaviour to contamination of the RG by the 1985 ejecta. Rushton et al. conclude that the RG is intrinsically variable. In addition we may expect strong effects due to inhomogeneities, a stellar wind and non-LTE (NLTE), but a consideration of these factors is beyond the scope of this paper. These phenomena affect the spectra of single canonical giants such as Arcturus (see the discussion in Tsuji 2009).

With the mass function from Fekel et al. (2000) and inclination from Fekel et al. (2000) and Ribeiro et al. (2009), we determine a mass of $\sim 2.25\,M_\odot$ for the RG if the WD is close to the Chandrasekhar limit. While the $^{12}\text{C}/^{13}\text{C}$ ratio after the first dredge-up is insensitive to the mass of the RG progenitor (and, of course, the situation in RS Oph is complicated by its binarity and RN eruptions), the $^{12}\text{C}/^{13}\text{C}$ ratio we find is consistent with this value because, on the basis of the $^{12}\text{C}/^{13}\text{C}$ ratio, we can probably exclude a progenitor mass for the RG below $\sim 1\,M_\odot$ (cf. fig. 2 of Charbonnel 1994). We can also of course conclude that the WD progenitor had a mass of $>2.25\,M_\odot$ so that some $0.8\,M_\odot$ of material has been deposited in the environment of RS Oph in addition to any material contributed by the RG wind.

6 CONCLUSIONS

We have carried out an analysis of a high-resolution spectrum of the RG component of the RN RS Oph. We find $^{12}\text{C}/^{13}\text{C} = 16 \pm 3$, which sheds new light on the history and evolution of the RS Oph system. The secondary star in RS Oph is an RG with a deficiency of carbon and an overabundance of nitrogen, as predicted by theories of the first approach to the RGB after the first dredge-up. The $^{12}\text{C}/^{13}\text{C}$ ratio we have found is consistent with the typical values (Smiljanic et al. 2009) observed in the atmospheres of RG stars in open clusters after the first dredge-up and further suggests that the RG in RS Oph has undergone some further mixing, which would have depressed the $^{12}\text{C}/^{13}\text{C}$ ratio still further.

Furthermore, in view of the strong variability of the CO bands following the 1985 (Harrison et al. 1993; Scott et al. 1994) and 2006 (Rushton et al. 2010) eruptions, it is important to monitor the IR spectrum of the RG in RS Oph to understand the reason for the changes observed.

We will provide a detailed analysis of abundances in the RG in RS Oph in forthcoming papers.
