S6.2 Resurgence of dermatophytosis infections, September 22, 2022, 4:45 PM - 6:15 PM

Objective: To present a series of cases of various types of dermatophytosis caused by *Trichophyton erinacei*, caused by contact with African hedgehogs.

Methods: Patients with clinical suspicion of ringworm caused by *T. erinacei* were included in the study. Each patient underwent a mycological study, with direct examinations (KOH), cultures in Sabouraud dextrose agar medium with and without antibiotics. With the cultures obtained, molecular identification was made using the PCR technique and Matrix Assisted Laser Desorption Ionization-Time of Flight (MALDI-TOF) proteomics. Once confirmed, the patients were given treatment and follow-up. When the pets (hedgehogs) were accessible, they were cultured with a cytobrush and the quills removed.

Results: In a period of 3.5 years, 14 verified cases were incorporated, 13 were females (72%) and 1 male (8%), the average age was 18.2 years, with the smallest one being 8 years old and the older 45 years old. The tinea manifested as follows: tinea manus 11 cases (68.7%), 2 respective cases of tinea corporis and tinea capitis (13.8% respectively) and one case of Majocchi’s granuloma. The average evolution was 1.5 months with the case older than 3 months and the younger 15 days. All cases were given terbinafine at variable doses and doses (according to weight and age) and clinical and mycological cure was obtained.

Discussion: Tinea can have epidemiological changes that are favored by a variety of factors, in general, pet ringworms are due to common domestic animals such as dogs and cats. Due to changing fashions, children and adolescents in recent years have changed pets such as hamsters, and recently hedgehogs, especially African variety (*Atelerix albiventris*) the latter may have *T. erinacei* as part of their skin microbiota, a smaller dermatophyte as they are part of the *T. mentagrophytes* complex, in general of low virulence, however, its antigenic variants are little recognized by humans, which makes them present in a very inflammatory form, particularly in the hands, due to the handling of the animal, as well as the deeper inoculation (in the dermis) by the spikes left by the inoculum. So, they can generate deep tineas such as Majocchi’s granuloma. In general, they respond well to systemic antifungals such as terbinafine and itraconazole, and sometimes the use of topical or systemic steroids is necessary.

Conclusions: This series of cases is a good example of how a change of habits when having pets can introduce new epidemiological agents that are poorly recognized antigenically, which give rise to more inflammatory and sometimes profound tineas.
S6.3c Adaptive dynamics in experimental populations of *Aspergillus nidulans*

S6.3 Fungal adaptation and evolution, September 22, 2022, 4:47 PM – 6:13 PM  

A total of 12 replicate populations initiated with a laboratory strain of the ascomycete fungus *Aspergillus nidulans* evolved on synthetic minimal glucose agar medium for 1 year, using weekly transfers of 3% of the produced aerial spores to fresh medium. This *Aspergillus* short-term evolution experiment (ASEX) was designed to understand how filamentous fungi adapt to growth on limited carbon in a spatially structured environment. We observed no systematic improvement in the fitness components sexual and asexual, in the competitive fitness relative to the ancestor. Instead, we observed the repeated evolution of at least two morphotypes, with a fluffy-like (FL) or an inconspicuous (IC) colony morphology, leading to inter-specific fitness interactions among isolates in two selected populations. The genomic analysis of clones from all 12 populations at an early (week 12) and the final time point (week 52), show a clear role of natural selection during ASEX. We also observed a shared genetic basis and different timing of adaptation of AL and FL types. In addition, in most populations, both morphotypes do not form monomorphic groups, but they frequently disappear and re-evolve from ancestral forms of both types. Reduction in aerial spore yield, the most evident parallel phenotypic change found in all 12 evolved populations, is not due to the direct selection of genes involved in aerial reproduction. Instead, we argue that reduced spore yield is a pleiotropic effect of adaptive changes in metabolism.

S6.4 One health approach for endemic mycoses in the Americas, September 22, 2022, 4:47 PM – 6:13 PM  

Objective: To present a series of cases of primary cutaneous coccidioidomycosis, to highlight this mycosis that can start as cutaneous implantation, after trauma, and to emphasize the classification criteria.  

Methods: A series of cases of primary cutaneous coccidioidomycosis will be presented, all of them confirmed by mycological studies, such as examinations, stains, and cultures, as well as their molecular identification, also confirmed by histopathology.  

Results: A series of 22 cases of primary cutaneous coccidioidomycosis is presented, 16 (72.8%) in men, 6 (27.2%) in women. With an average age of 35.2 years, the longest case in 14-year-old child and the highest in 72 years. All from rural and endemic areas. A total of 11 (50%) with skateboard and the rest due to various injuries. The etiological agent was isolated in all of them: Coccidioides posadaii in 14 (72.8%), C. immitis in 3 and one by Coccidioides sp. 20 cases were managed with itraconazole, with an average of 8 months and two more with a cycle of amphotericin B and subsequent itraconazole. Clinical and mycological cure was obtained in all.  

Discussion: Primary cutaneous coccidioidomycosis is considered an implantation mycosis, similar to other endemic ones, it occurs between 2%-10% of cases. It begins after trauma that inoculates the fungi, such as a primary chance. To confirm that it is a primary form, Wilson’s criteria must be met: the presence of skin trauma, regional lymphadenopathy, no evidence of pulmonary involvement, positive intradermal reaction, and low antibody titer. It may present auto-inoculation and in immune-suppressed patients, it can spread.  

Conclusion: The cutaneous form of coccidioidomycosis is rare, usually seen in patients living in endemic areas, and usually present in patients with cutaneous infections. It has a variety of clinical forms, being confused with several diseases. Its diagnosis is simple, being the biopsy the most used, and it must be confirmed by mycological tests. It has a good prognosis and its main management is with itraconazole.
