Key words: accretion and accretion discs – hydrodynamics – turbulence

Abstract

A thin gaseous disc with an almost keplerian angular velocity profile, bounded by a free surface and rotating around point-mass gravitating object is nearly spectrally stable. Despite that the substantial transient growth of linear perturbations measured by the evolution of their acoustic energy is possible. This fact is demonstrated for the simple model of a non-viscous polytropic thin disc of a finite radial size where the small adiabatic perturbations are considered as a linear combination of neutral modes with a corotational radius located beyond the outer boundary of the flow.

1 Introduction

Accretion discs are observed astrophysical objects which can transform a high fraction of gravitational energy to thermal energy and electromagnetic radiation. The fact of effective conversion of the smooth large-scale rotation to the small-scale dissipative chaotic structures indicates that the shear flows constructing an astrophysical discs must exhibit hydrodynamical activity, in other words, must be able to generate complex motions that strongly increase the shear viscosity, and cause the angular momentum transfer. Furthermore, the numerous observations of variabilities in discs that already endure the action of the accretion mechanism imply that these discs may also give birth to non-stationary large-scale deviations from the basic flow.

Theoretical analysis of the stability of astrophysical discs and dynamics of various perturbations in them has been performing through decades. At present moment, however, the picture is not complete even for the simplest models of the shear flows. The same can be told about the linear theory when one considers a small perturbations only. In this case the obstacle is that the traditional eigenvalue approach to evolution of oscillations and waves in shear flows when it is assumed that the solution has the form of definite frequency Fourier components $e^{i\omega t}$ has revealed to be ineffective while studying the initial value problems. It turned out that even in the flows which are stable in a sense that all perturbation modes are exponentially damping it is possible to set up such initial deviation from the background that it will be followed by a substantial transient growth of perturbations on the dynamical time-scale. Mathematically, this is closely related to the non-orthogonality of modes in any physically meaningful metric space associated with them or, equivalently, to the non-normality of the appropriate linear dynamical operator.

One of the first reviews on this subject has been done by Trefethen et al. (1993) and the studies of certain models were carried out in the framework of non-modal approach by Butler & Farrell (1992), Farrell & Ioannou (1993), Henningson & Reddy (1994), Hanifi et al. (1996) and many others. The necessary references can be found in book by Schmid & Henningson (2001) and in the latter review by Schmid (2007). Among other things, the so-called 'bypass mechanism' for the onset of turbulence has been formulated. The concept states in general that the linear transient growth of optimal perturbations is a physical phenomenon responsible for the energy transfer between the large-scale motion and stochastic vortices. Apart, the interaction between vortices themselves plays only a conservative role producing the stationary phase space distribution of vortices which is required to preserve modes taking part in energy transfer.

In astrophysical community the work by Ioannou & Kakouris (2001) paid more attention to new ideas on the non-modal approach in hydrodynamical theory of perturbations. The authors analysed the spectrally stable two-dimensional flow of incompressible fluid rotating with the keplerian angular velocity profile and showed that a stochastic external forcing in a form of white noise leads to the formation of strongly increased coherent structures that carry an angular momentum outwards.

It fact, the first studies in the area were published yet in the 1980s but have been performed in a slightly different form. We are talking about papers by Lominadze et al. (1988) and Fridman (1989), where the local evolution of an arbitrary initial vortical perturbations was considered. The local analysis of an astrophysical disc dynamics has been utilized since the work by Goldreigh & Linden-Bell (1965). In that framework assuming the constant shear in the radial direction it makes sense to change to co-moving shearing coordinate system to implement calculations for
the spatial Fourier harmonics (SFH) of perturbations. Thus, one analytically obtains the evolution of all possible initial perturbations and as well as the behaviour of their part exhibiting transient growth. Let us remind that according to Fjortoft’s theorem (1950) the constant shear flow constructed of incompressible and non-stratified fluid is asymptotically stable since it has no vorticity extremum.

We would also like to mention Chagelishvili et al. (1996) who proposed a qualitative explanation of the transient growth phenomenon and Chagelishvili et al. (1997) who discussed a peculiar transformation of vortical SFH to the sound waves. In the latter and several subsequent papers (Tevzadze et al. 2003, Bodo et al. 2005, Tevzadze et al. 2008, Tevzadze et al. 2010) in addition to the energy extraction from the background a new process of the linear coupling of SFH is examined. The linear coupling of SFH leads to the mutual energy exchange between SFH of different types that correspond to fluid properties involved in calculations, namely, it’s compressibility and stratification in the radial and vertical directions. Here we can draw an analogy to the well-known resonant interaction (called ‘coupling’ as well) of modes in a critical layer where the pattern speed of modes equals to the angular velocity of the flow (Cairns 1979).

The local analysis in non-modal approach was also employed for different basic configurations by Yecko (2004), Afshordi et al. (2005), Mukhopadhyay (2005), Mukhopadhyay (2006), Johnson & Gammie (2005a,b), recently by Volponi (2010) and others.

Let us note, however, that despite the clear indications of the substantial transient growth found for a variety of disc models in the studies quoted above the transition to turbulence through bypass mechanism is seriously questioned by comprehensive numerical simulations performed by e.g. Lesur & Longaretti (2005), Shen et al. (2006), Rincon et al. (2007), Lesur & Papaloizou (2010). So the other ways to transition can’t be excluded, for instance, by some kind of secondary instability (see the recent paper by Mukhopadhyay & Kanak 2011).

Nevertheless, the non-orthogonality of modes may become crucial in the non-stationary appearance of turbulent viscous astrophysical discs. The studies by e.g. Umurhan et al. (2006), Regev (2008) and Rebusco et al. (2009) (see also Shtemler et al. 2010) provide some evidence for that. They considered thin accretion discs with an $\alpha$-parametrization of viscosity which revealed a high transient growth of perturbations of density and vertical velocity component caused by the specially selected initial oscillations of the velocity in the disc plane. Note that in contrast to numerous investigations done in the framework of local analysis these studies involved large-scale vertical and radial structure of the disc.

In this paper we concerned with the global optimal adiabatic perturbations, i.e. perturbations exhibiting the highest possible transient growth in the fixed time interval. We would like to set up perturbations in thin non-viscous disc with a nearly keplerian rotational profile. A simple barotropic configuration of a finite radial size bounded by a free surface where the pressure vanishes is an object for our considerations. Due to small corrections set by the pressure gradient angular velocity, $\Omega$, will decrease slightly steeper than the keplerian one, $\Omega_K \propto r^{-3/2}$, as the radial distance, $r$, grows. Lots of calculations by means of an eigenvalue analysis (see e.g. Koijima 1989 and Hawley 1990 with references therein) in such configuration show that it has an exponentially growing modes, though the increments become noticeable only for considerable pressure gradient in the flow when the rotation is essentially non-keplerian.

Present study is motivated by the previous work by Zhuravlev & Shakura (2009, ZS hereafter) where the optimal perturbations were found for a similar two-dimensional flow with a power law rotational profile $\Omega \propto r^{-q}$, where
$3/2 < q < 2$. It was revealed that, first, the strongest transient growth was produced by the linear combinations of slow sound modes with a corotation radius beyond the outer boundary of the flow, and second, the transient growth intensified while $q \to 3/2$, i.e. while the rotation tends to keplerian one.

Hence, we would like to examine the flows with an almost keplerian rotation what leads to a small $\delta = H/r$, where $H$ and $r$ are the characteristic half-thickness and radial size. The smallness of $\delta \ll 1$ makes it possible to find the disc sound modes analytically employing the WKBJ scheme. As ZS we will extract optimal perturbations from span of the linear combinations of sound modes.

2 Stationary flow

2.1 Basic assumptions

Let us consider the axisymmetric flow in an external Newtonian gravitational potential $\Phi \propto -1/R$, where $R = (r^2 + z^2)^{1/2}$ is distance from gravitating body and we will use the cylindrical coordinate system below $\{r, \varphi, z\}$. We confine ourselves to the case of perfect fluid and polytropic configuration with an equation of state $p = K \rho^{1+1/n}$, where $p$ and $\rho$ are the pressure and mass density of material and $n$ is the polytropic index. Introducing enthalpy $h = \int dp/\rho$ we write equations of motion for the rotating stationary flow

$$\begin{align*}
\frac{\partial h}{\partial r} &= \Omega^2 r - \frac{\partial \Phi}{\partial r}, \\
\frac{\partial h}{\partial z} &= -\frac{\partial \Phi}{\partial z},
\end{align*}$$

(1)

where in our model $\Omega = v_\varphi/r$ can be an arbitrary function of the radial coordinate $r$. Following the previous studies we set it to be a power law

$$\Omega = \Omega_0 \left(\frac{r}{r_0}\right)^{-q}$$

(2)

Here $r_0$ is the distance from the central body at which the rotation has a keplerian angular velocity $\Omega_0$ in the midplane $z = 0$.

Equalities (1) allow us to find the distribution of enthalpy in the flow

$$h = (\Omega_0 r_0)^2 \left[(x^2 + y^2)^{-1/2} - x_1^{-1} + \frac{1}{2(q-1)} \left(x_1^{-2(q-1)} - x^{-2(q-1)}\right)\right],$$

(3)

where the dimensionless coordinates are introduced $x \equiv r/r_0$, $y \equiv z/r_0$. In this model of the basic configuration it’s free boundary corresponds to the surface $h = 0$ and $x_1 < 1$ is the crossing of that surface by an equatorial plane $y = 0$. It is easy to show that in some range of the values of $q$ there is always a second crossing $x_2 > 1$. Let us call $x_1$ and $x_2$ simply the inner and the outer boundary of the flow and $x_d = x_2 - x_1$ it’s radial size. Here we are concerned with the configurations of a finite radial size $x_d < \infty$.

2.2 Thin disc

The situation when the rotational profile is almost keplerian is the most interesting to us. Let $q = 3/2 + \epsilon^2/2$, where $\epsilon \ll 1$. Then, using the smallness of $\epsilon$, and retaining in (3) only the main terms in orders of $y^2$ and $\epsilon^2$, we get an
expression for the shape of the flow boundary, i.e. its half-thickness profile

\[ H(x) = 2^{1/2} \epsilon x [1 + \ln x - (x/x_1)(1 + \ln x_1)]^{1/2} \]  

(4)

Looking at (4) one can see that for moderate radial size \( x_d \sim 1 \) the half-thickness is controlled by the value of \( \epsilon \) and we have stationary configuration in a form of the thin disc with \( H/x_d \ll 1 \).

Entering a new variable \( \delta \equiv H(x = 1) \) which is approximately the maximum half-thickness in disc we finally have

\[ H = \delta x \left[ \frac{x_1(1 + \ln x) - x(1 + \ln x_1)}{x_1 - 1 - \ln x_1} \right]^{1/2} \]

\[ h = \frac{H^2}{2x^3} \left[ 1 - \left( \frac{y}{H} \right)^2 \right], \]

(5)

where enthalpy is dimensionless.

The relations (5) completely specify the polytropic disc where we are going to impose perturbations.

### 3 Spectral problem

The spectral problem implies calculation of definite frequency eigen-modes of perturbations for the specified stationary flow. Non-viscous perturbation modes of small amplitude, \( \propto \exp(-i\omega t + m\varphi) \), which obey the equation of state common with the basic flow are described by the following equation

\[
\frac{D}{x \rho} \frac{\partial}{\partial x} \left( x \rho \frac{\partial W}{\partial x} \right) - \frac{D}{\rho \omega^2} \frac{\partial}{\partial y} \left( \frac{\partial W}{\partial y} \right) - \left[ \frac{2m D}{\omega} \frac{\partial}{\partial x} \left( \frac{\Omega}{D} \rho \right) + \frac{D}{a^2} + \frac{m^2}{x^2} \right] W = 0
\]

(6)

Here \( W = \bar{p}/\rho \) is the function to be determined, \( \bar{p}(x, y) \) is a Fourier amplitude of the pressure perturbation, \( a \) is a sound speed in the mean flow.

In (6) the following characteristic frequencies and its combinations have been assigned: the shifted frequency of mode \( \bar{\omega} = \omega - m\Omega \), the epicyclic frequency squared \( \kappa^2 = \frac{\partial}{\partial x} \left( \Omega x^2 \right) \), and the combination \( D = \kappa^2 - \bar{\omega}^2 \).

Derivation of (6) has been discussed by many authors, see e.g. Goldreich (1986), Kojima (1989), Kato (1987), one may also read a review by Kato (2001) on the oscillations in thin discs.

The boundary condition at the disc surface goes from equality to zero of the Lagrangian perturbation of pressure, which in turn is equivalent to regularity condition for \( W \) at the boundary

\[ W + \frac{1}{D} \frac{\partial h}{\partial x} \left( \frac{2m\Omega}{x \bar{\omega}} W - \frac{\partial W}{\partial x} \right) + \frac{1}{\bar{\omega}^2 \frac{\partial}{\partial y}} \frac{\partial W}{\partial y} = 0 \]

(7)

A complete solution of the system (6-7) and the determination of the whole spectrum of disc eigen-modes is a challenge for anyone. An eigen-frequency \( \omega \) is in general a complex number what corresponds to exponentially growing and damping oscillations.

It is well known fact that either growth or attenuation of the particular modes take place only if the corotation point, \( x_c \), where \( \dot{R}c(\omega) = m\Omega \), is located inside the flow since energy exchange either between the modes and the background or between the modes themselves having the total energy of opposite signs is possible solely in the vicinity of \( x_c \) (for details look in the book by Stepanyants & Fabrikant 1996 and in the papers by Papaloizou & Pringle 1987, Narayan et al. 1987, Glatzel 1987 with references therein) The energy exchange in described by the resonant
denominator in the coefficient of the basic equation \((6)\), and the corotation point \(\omega = m\Omega\) is its singular point. The solution is multi-valued in the vicinity of that singular point what causes the problem of choice of a physically relevant branch what can be done according to the Lin’s rule (1945). Additionally, Lindblad resonances given by \(D = 0\) are the removable singularities of \((6)\) but they are also of certain importance in perturbation dynamics.

However, we are interested in the non-modal dynamics here so let us choose the part of the spectrum that will be easy to obtain. Specifically, we consider the modes rotating slower than the flow itself, i.e. with a corotation radius \(x_c > x_2\). As was pointed out in ZS that is these modes that are able to exhibit the most considerable transient growth. Note that every such mode is neutral and have a constant total energy. We assume additionally that Lindblad resonances are out of the flow as well. (the corresponding condition will be formulated below) Hence, in \((6)\) the term \(\propto a^{-2}\) in coefficient in front of \(W\) is large everywhere in disc. This implies that the wavelength of perturbations \(\lambda\) is small and comparable to the disc thickness \(\lambda \sim H \ll x_d\). As it was shown by Nowak & Wagoner (1992), see also Kato (2001), equation \((6)\) is separable in the lowest WKBJ order into horizontal and vertical parts coupled by the slowly varying function \(\Lambda(r)\).

However, here we would like to do further simplification and consider perturbations with no nodes in the vertical direction, so that \(W\) is the function of \(x\) only. Formally, this means that we require the maintenance of the vertical hydrostatic equilibrium in perturbed motion. This is of course a questionable requirement that artificially restricts our investigation especially taking into account that strict vertical equilibrium in the perturbed flow is possible for certain type of modes in case of isothermal vertical structure of the disc. So the general case \(W(x, y)\) should be considered in the subsequent study.

Thus, all mentioned assumptions allow us to use the WKBJ approximation to determine the profiles of inertial-acoustic modes on interval \((x_1, x_2)\).

### 3.1 Calculation of modes

We first integrate the equation for small perturbations over the vertical direction obtaining

\[
\frac{D}{x\Sigma} \frac{d}{dx} \left( \frac{x\Sigma dW}{D} \frac{d}{dx} \right) - \left[ \frac{2m}{\omega} \frac{D}{x\Sigma} \frac{d}{dx} \left( \frac{\Omega\Sigma}{D} \right) + \frac{n + 1/2}{2} \frac{D}{h_*} + \frac{m^2}{x^2} \right] W = 0
\]

(8)

where

\[
\Sigma(r) = \int_{-H}^{H} \rho dz \propto H \left( \frac{H^2}{x^3} \right)^n \quad \text{and} \quad h_* = \frac{H^2}{2x^5}
\]

(9)

are the surface mass density of the disc and enthalpy in the midplane of the disc correspondingly.

Note that after a change \(n \rightarrow n - 1/2\) provided that \(x_d < 1\) equation \((8)\) coincides with the analogous equation in two-dimensional problem which arises if we assume that perturbations are localized near the midplane of the disc, i.e. if in \((6)\) all background quantities are equated to their equatorial values. This result was used to check the analytical solutions given below with the numerical calculations performed for two-dimensional problem in ZS (see also Zhuravlev & Shakura 2007).

Then, for part of the spectrum we have chosen the inner Lindblad resonance must be located outside of the flow, so that
what is followed by $D < 0$ and the WKBJ approximation gives an oscillating solutions. Let us note that in the case $m = 1$ the inner Lindblad resonance is shifted to $x = 0$ in the non-relativistic limit, consequently, disc settles into the evanescent zone for any arbitrary small frequency. Thus, we only consider modes with $m > 1$.

Then, it is convenient to write the WKBJ-solution in the form

$$W = C_0 S_1 \cos(S_0 + \varphi_0), \quad (11)$$

where

$$S_0 = \int_{x_1}^{x} \left( (n + 1/2) \frac{-D}{h_*} - \frac{m^2}{x^2} \right)^{1/2} dx,$$

$$S_1 = \left( \frac{D}{x^\Sigma} \right)^{1/2} \left( (n + 1/2) \frac{-D}{h_*} - \frac{m^2}{x^2} \right)^{-1/4},$$

and $C_0$ and $\varphi_0$ are constants specified by the boundary conditions. Note that following WKBJ scheme we retain the terms in two main orders of $\delta$ proportional to $\propto \delta^{-2}$ and $\propto \delta^{-1}$. For that reason the first term in coefficient in front of $W$ as it stands in equation (8) is absent in (11). For similar reasons combination $D$ entering (11) is evaluated for a pure keplerian rotation.

WKBJ solution (11) is irregular in the boundary points $x_1$ and $x_2$. On the contrary, we mentioned above that the regularity of $W$ at $x_{1,2}$ is equivalent to the boundary condition. Let us change to new independent variable $\tilde{x} \equiv |x - x_{1,2}|$ and rewrite equation (8) in case of $\tilde{x} \ll 1$. Practically, we assume that all quantities in (8) having finite values at $x_{1,2}$ are equal to these values and approximate the disc half-thickness which vanishes at $x_{1,2}$ by the main term in it’s expansion over $\tilde{x}$ getting

$$H = H_{1,2} \tilde{x}^{1/2}$$

where

$$H_{1,2} = \delta x_{1,2} \left| \frac{\ln x_{1,2}}{1 + \ln x_{1,2} - x_{1,2}} \right|^{1/2}$$

In this way we get

$$\tilde{x} \frac{d^2 W}{d\tilde{x}^2} + (n + 1/2) \frac{dW}{d\tilde{x}} + E_{1,2} W = 0 \quad (12)$$

where

$$E_{1,2} = \frac{(2n + 1)(-D_{1,2}) x_{1,2}^2}{H_{1,2}^2}, \quad D_{1,2} \text{ are the values of } D \text{ in } x_{1,2}$$

The solution of (12) which is regular at $x_{1,2}$ is the following

$$W = C_{1,2} \tilde{x}^{-(2n-1)/4} J_{n-1/2}(\tilde{z}), \quad (13)$$

where $\tilde{z} = 2E_{1,2}^{1/2} \tilde{x}^{1/2}$.

Since the denominator of $\tilde{z}$ contains small $\delta$, at some distance from the boundary points $\tilde{z} > 1$ while $\tilde{x} < 1$. In this domain we take for $W$ an approximate expression using the asymptotic expansion of the Bessel function in (13) getting

\[\text{at the same time we retain the term } \propto m^2 \text{ since we may consider modes with } m >> 1 \text{ as well}\]
\[ W \approx C_{1,2} \bar{x}^{-n/2}(4\pi^2 E_{1,2})^{-1/4} \cos \left(2E_{1,2}^{1/2} \bar{x}^{1/2} - n \pi/2 \right) \]  

Matching (14) for the expansion of the WKBJ solution (11) in the vicinity of \( x_1 \) and \( x_2 \) gives the zero phase \( \varphi_0 = -n\pi/2 \) and the dispersion relation

\[
\int_{x_1}^{x_2} \left( (2n+1) - \frac{Dx^3}{H^2} - \frac{m^2}{x^2} \right)^{1/2} dx = \pi(n+k),
\]

where \( k \) is an integer number.

Thus, the profiles of modes are given by the expressions (11) and (13) taking into account the following relations for constants

\[
\frac{C_0}{C_1} = \left( \frac{H_1^{2n+1}}{2\pi x_1^{3n-1}(-D_1)} \right)^{1/2}, \quad \frac{C_2}{C_1} = (-1)^k \left[ \left( \frac{x_2}{x_1} \right)^{3n-1} \frac{D_2}{D_1} \left( \frac{H_1}{H_2} \right)^{2n+1} \right]^{1/2}
\]

### 4 Optimal growth of perturbations

In present study we utilize common procedure to calculate an optimal growth \( G(t) \) for a linear combination of modes (for details see sect. 3.1 ZS and references therein). As in ZS we measure the growth of perturbations by their total acoustic energy

\[
E_a = \frac{1}{2} \int \Sigma \left( \delta v_r^2 + \delta v_\varphi^2 + (n + 1/2) \delta h \right) x dx d\varphi,
\]

where \( \delta v_r, \delta v_\varphi \) and \( \delta h \) are the Euler perturbations of radial and azimuthal velocity components and enthalpy and the integration over the whole flow is implied.

The slight difference in comparison with ZS is that we integrate the energy density over \( z \) what results in the emergence (see eq. (6) of ZS) of an additional factor \( n + 1/2 \) in term \( \propto h^{-1} \) and the volume density is replaced by the surface density [9].

The metrics \( M \) in the linear span of the particular set of modes is calculated numerically taking the analytical expressions for the dispersion relation and profiles of \( W \) obtained above.

Then, matrix of propagator acting on the initial perturbations is diagonal in the basis constructed of modes

\[ \Lambda = \text{diag}\{\exp(-i\omega_1), \exp(-i\omega_2), ..., \exp(-i\omega_N)\}, \]

where \( \omega_j \) are the frequencies of those modes.

With the metrics determined we change to orthonormal basis where \( \Lambda \) transforms into non-diagonal and non-normal matrix. It’s norm squared equals to it’s 1st singular value which is \( G(t) \).

An example of \( G(t) \) at time intervals of order of the sonic time \( t_s \sim (\delta\Omega_0)^{-1} \) and at the longer periods in comparison with the dynamical timescale \( t_d \sim \Omega_0^{-1} \) is displayed in Fig. 1.

Also one can see there the evolution of certain optimal combinations of slow modes, \( g(t) \) (see eq. (10) of ZS). We draw time in units of the keplerian periods \( t_0 = 2\pi\Omega_0^{-1} \) on the horizontal axis. Curves \( g(t) \) are associated with perturbations that reach the highest possible (in linear problem) growth at \( t = 250, 290, 340 \), when as it should be they touch with the overall curve corresponding to optimal growth \( G(t) \).

As seen from Fig. 1 \( G(t) \) has a quasi-periodical shape repeatedly reaching the peaks and perturbations increase by many times at intervals of several hundreds of \( t_0 \). Clearly, this corresponds to sonic time-scale \( t_s \), and we keep in
mind that even if there is a turbulent viscosity which switches on an accretion in disc the whole configuration evolves at the diffusion time-scale $t_\nu \sim \delta^{-2} t_d$. Thus, we conclude that the revealed transient dynamics in non-viscous rotating flow is possibly relevant to thin accretion discs at the intermediate time intervals in comparison with dynamical and viscous time-scales.

### 4.1 Angular momentum flux

Now we are concerned with the redistribution of the specific angular momentum during the transient dynamics. With the help of Savonije & Heemskerk (1990) results let us write an appropriate expression for the angular momentum flux density of perturbations in the radial direction (see sect. 4 of work by Savonije & Heemskerk 1990)

$$F = x\Sigma < \delta v_r, \delta v_\phi >,$$

where brackets $<>$ mean an azimuthal average.

Note that $F$ is directly related to another important quantity describing the evolution of perturbations which is the flux density, $F_R$, of energy transferring from the background. $F_R$ is called also a Reynolds force and $F_R = -d\Omega/dxF$. Clearly, $F_R$ and $F$ have the same sign in our case, positive when angular momentum is transferred outwards and
perturbations take energy from the background meanwhile (the epoch of $g(t)$ increase) and negative in the opposite situation (the epoch of $g(t)$ decrease). Also note that following the spectral analysis it is easy to show that for any mode separately $F = 0$ in the whole range between $x_1$ and $x_2$.

Figure 2: The radial shapes of azimuthally averaged angular momentum flux density $F$ of transient perturbations are presented (Angular momentum density has only vertical non-zero component in our model). The curves correspond to evolution of a particular combination of modes which can be seen on the left-hand panel in Fig. 1 as $g(t)$ for optimization moment $t = 290$. On the left-hand panel: the curves are obtained at $t = 50, 100, 150, 200, 240$ before $g(t)$ attains it’s maximum value. Each profile has one high peak with it’s position shifting from the outer boundary to the inner boundary as time goes on. On the right-hand panel: the curves are obtained at $t = 290, 350, 400, 450$ after $g(t)$ attains it’s maximum value. Each profile has, analogously, one deep minimum with it’s position shifting from the inner boundary to the outer boundary as time goes farther. On both panels: the dimension of a linear combination $N = 20$, the other parameters are $\delta = 0.002, \alpha_d = 1.0, m = 25, n = 3/2$.

It is quite straightforward to calculate $F$ profile for optimal perturbations. In Fig. 2 we see how the shape of $F$ transforms during the evolution of certain optimal combination of modes associated with the moment $t = 290$ (when it touches the curve $G(t)$) in Fig. 1. The moment $t \approx 290$ coincides with the local peak of $g(t)$ in this particular case.

It turns out that the specific angular momentum alters at rate varying along the interval $(x_1, x_2)$. More definitely, the highest angular momentum flux and the most rapid alternation of angular momentum density is always localized in some narrow part of $(x_1, x_2)$.

As $E_a$ increases the mentioned domain of an intensive angular momentum outflow shifts from the inner to the outer boundary of disc. After the transient growth attains it’s peak the abrupt turnover happens with $F$ so that angular momentum starts to flow towards the inner boundary. The latter result is expected since we are dealing with the nearly stable configuration. Clearly, the domain of the most intensive inflow of angular momentum appears first near the inner boundary and then moves to the outer boundary.
4.2 Parametric study

In this section we briefly discuss the dependence of $G$ on the free parameters of the problem. They are the azimuthal wavenumber $m$, the polytropic index $n$, the typical half-thickness of disc given by $\delta$ and the radial size of the disc $x_d$. Besides, we have to fix the number of modes, $N$, involved in calculations, i.e. the dimension of the linear span for perturbations we consider. However, the numerical tests show that a kind of saturation of the transient growth occurs as $N$ increases. In other words, as we include more and more modes the magnitude of $G$ stops to rise up noticeably from some value of $N$. This is illustrated by Fig. 3 where we present the dependence of magnitude of the first peak at $G$ curve, $G_{\text{max}}$, on $n$ obtained for different $N$. Note that this saturation upon reaching $N \sim 30 - 40$ takes place for the model of ZS as well. The polytropic index varies in the range from $3/2$ to 3 what means passing from non-relativistic to relativistic gas in case of the flow with a zero gradient of entropy. We conclude that $G_{\text{max}}$ is almost independent of $n$.

![Graph showing $G_{\text{max}}$ vs. $n$](image)

Figure 3: The first peak of an optimal growth curve, $G_{\text{max}}$, depending on the polytropic index, $n$, calculated for various dimensions of a linear combination $N$. From bottom to top: $N = 4, 8, 12, 16, 20, 24, 28$. The other parameters are $\delta = 0.01$, $x_d = 2.0$, $m = 15$.

Then, in Fig. 4 we demonstrate how $G_{\text{max}}$ depends on $\delta$ which is the key parameter of our model. This is done for several values of $m$. On the right-hand panel of Fig. 4 one can see also the curve of $T_{\text{max}}(\delta)$ where $T_{\text{max}}$ is the time interval given by the condition $G(T_{\text{max}}) = G_{\text{max}}$. As we see $G_{\text{max}}$ increases inversely to the half-thickness of the disc what is consistent with the results of ZS where the similar dependence on the Mach number was presented. Additionally, the substantial dependence on $m$ is confirmed here. Precisely, $G_{\text{max}}$ is proportional to the azimuthal wavenumber. Apart, the approximate duration of the transient growth given by $T_{\text{max}}$ alters weakly with $m$. At the same time concerning it’s dependence on the half-thickness one can find the relation $T_{\text{max}} \sim (\delta \Omega_0)^{-1}$ corresponding to sonic time-scale what has been already discussed above.

\[2\] Small variations of $G_{\text{max}}$ in Fig. 3 are actually caused by the fact that while moving through the parameter space one has to adjust slightly the set of neutral modes to satisfy the condition \[\text{III}\]. As should be noted we always take the first neutral modes as measured by the distance of their corotation point from $x_2$. 

11
Finally, in Fig. 5 it is displayed how $G_{\text{max}}$ and $T_{\text{max}}$ alter with variation of $\delta$ for few values of $x_d$. As we see both quantities grow as $x_d$ increases in agreement with ZS.

5 Discussion

In this paper we reveal the significance of the linear transient dynamics concept in application to astrophysical discs. We point out that in contrast to the majority of studies in the area the global problem was considered, i.e. the perturbation dynamics was examined in the whole disc taking into account it’s free boundary. Moreover, we employ the approximation of thin disc with an almost keplerian rotation. The latter is quite important in astrophysics. However, several simplifications have been done to obtain the results. First, we neglect the viscosity in disc and assume it to be barotropic. Then, we consider only perturbations that preserve the vertical hydrostatic equilibrium. And after all we make one more assumption taking the linear combinations of neutral modes only. We call these neutral modes “slow modes” since their corotation radii are beyond the outer boundary of the disc.

Nevertheless, even the oversimplified model shows that thin disc is able to generate perturbations with a substantial transient growth. Further, to the contrary with the conclusions of modal analysis an optimal growth gets higher with the decrease of disc thickness $\sim \delta$, see Fig. 4 and Fig. 5. Let us remind that sonic instability, i.e. an exponential growth of sound modes generated by a similar toroidal configurations ceases promptly as one passes towards the keplerian rotation. Note again that the total energy of each neutral mode remains constant in time and azimuthally.
Figure 5: The dependence of $G_{\text{max}}$ (left-hand panel) and $T_{\text{max}}$ (right-hand panel) on $\delta$. On both panels: from low to upper curves $x_d$ has the values correspondingly $x_d = 0.5, 1.0, 1.5, 2.5$. The other parameters are $N = 20$, $m = 10$, $n = 3/2$.

averaged radial component of angular momentum flux density corresponding to that mode equals to zero at any point of $(x_1, x_2)$. But nothing like that belongs to the linear combination of those modes which exhibits a considerable growth of an acoustic energy (see Fig. 1) accompanied by the increasing outflow of the specific angular momentum to disc periphery (see Fig. 2).

We find that the transient growth acts on the time-scale $\sim (\delta\Omega_0)^{-1}$, intermediate between the dynamical $\sim \Omega_0^{-1}$ and viscous $\sim \delta^{-2}\Omega_0^{-1}$ timescales. This implies that optimal perturbations can grow up much faster than disc structure changes under the action of viscous forces causing a gradual diffusive angular momentum transfer. Consequently, the transient dynamics phenomena can be important in accretion disks that already have a constant turbulent viscosity. Though, one must keep in mind that in highly viscous discs the viscous forces should be allowed for changing the dynamics of perturbations themselves since their characteristic scale $\lambda$ is small $\lambda \sim \delta$ and the corresponding time-scale is comparable to the dynamical one.

The latter suggestion can be treated as one of the ways to develop the present study. Besides that, it would be possible to formulate problem on the stochastic forcing of the disc what was considered by Ioannou & Kakouris (2001) for their shearing flow model. Note that we take into account compressibility of medium and the presence of the free boundaries. However, perhaps the more important development of the research is to include the vertical motions in the perturbed flow, i.e. to include the dependence of perturbations on the vertical coordinate. The results of Rebusco et al. (2009) indicate that this can reveal even more intensive transient dynamics.

To conclude, let us remind that we take merely the modes without the turning points (Lindblad resonances) and the evanescent WKBJ-zone inside $(x_1, x_2)$. Additionally, the nearest Lindblad resonance is restricted to lie outside of
the flow at some small distance \( d_L \sim \delta \) beyond the outer boundary in order for WKBJ scheme to be valid everywhere in \((x_1, x_2)\) and to match smoothly a WKBJ-solution for an asymptotic expansion of a boundary solution close to \(x_2\), see above. However, the numerical tests showed that magnitude of the transient growth is sensitive to the presence of modes that have the mentioned Lindblad resonance the most close to \(x_2\). That is why it would be desirable to include into consideration modes with resonances inside the flow.
