Abstract

Tunneling between the two lowest energy levels of single molecule magnets with Ising type anisotropy, accompanied by the emission or absorption of phonons, is considered. Quantitatively accurate calculations of the rates for such tunneling are performed for a model Hamiltonian especially relevant to the best studied example, Fe₈. Two different methods are used: high-order perturbation theory in the spin-phonon interaction and the non-Ising-symmetric parts of the spin Hamiltonian, and a novel semiclassical approach based on spin-coherent-state-path-integral instantons. The methods are found to be in good quantitative agreement with other, and consistent with previous approaches to the problem. The implications of these results for magnetization of molecular solids of these molecules are discussed briefly.

I. INTRODUCTION AND BACKGROUND

Single molecule magnets, also known as molecular nanomagnets, are a twenty-year old class of magnetic materials consisting of organomagnetic molecules that form molecular solids. Their general characteristics are a total spin of about 10 per molecule in the ground state, an absence of exchange interaction between different molecules, and magnetic anisotropy with an energy difference per molecule of tens of Kelvin between easy and hard directions [1, 2]. The most studied systems, Fe$_8$ and Mn$_{12}$, both have spin magnitude $j$ equal to 10, and uniaxial Ising-type anisotropy. At low enough temperatures, only the $m = \pm 10$ Zeeman levels are occupied. On theoretical grounds, transitions between these two levels can only take place via quantum tunneling, and for Fe$_8$ there is clear evidence that such tunneling really occurs [3], even though the tunneling matrix element is only $10^{-8}$ K or 1 peV in energy units. However, quantum tunneling with significant probability transfer between the states involved can only happen if the states are nearly degenerate in energy. If they are not, the tunneling degree of freedom (in this case the spin) must be coupled to an environment which can supply or absorb the energy necessary to maintain energy conservation. This fact, coupled with the general paucity of excitations with large energy, greatly restricts the dynamics of the total magnetization of the solid. Several experiments [4–11] find that magnetization relaxation is slow, with non-exponential behaviour in time.

The current theoretical understanding of this slow relaxation [12, 13] is that interaction of the molecular spins with the nuclear spins renders the quantum tunneling of the former incoherent, but because the nuclear spins that couple to a given molecular spin can exchange only a rather limited amount of energy, the requirement of near-degeneracy of the Zeeman levels of the molecular spin is weakened only moderately, and the two levels must lie within a narrow window of each other in order for transitions to occur. Further relaxation can only take place due to the intermolecular dipole field, which can be quite inhomogeneous. If this field happens to be such at a given molecular spin site as to bring that spin into near degeneracy, it will be able to flip. This flip will change the field at other sites, potentially allowing those spins to relax. Monte Carlo and kinetic equation studies based on this model have been done by several authors [14–19], all of whom obtain slow relaxation, and in some cases, an initial square-root time dependence as seen experimentally.

A central feature of the above model is that the transition rate between the $m = \pm j$ levels
is insensitive to which one is lower in energy. It thus allows the magnetization of a bulk sample to relax without relaxation of the energy, and the relaxation is always toward the state of zero magnetization. As a result, this model cannot explain magnetization experiments in which a magnetic field is applied to an initially demagnetized sample. In this case, it is essential to understand the relaxation of energy as that is what drives the change in magnetization from zero to a nonzero value.

The obvious environment to which energy can be transferred is the phonons. The immediate puzzle is that the spin-phonon interaction typically involves processes with $\Delta m = 1$ or $\Delta m = 2$, while in the cases of Fe$_8$ and Mn$_{12}$, we require $\Delta m = 20$. Thus the relaxation must take place via a combination of spin tunneling and phonon emission. If we accept this hypothesis, the program of understanding the magnetization experiments in molecular magnetic solids divides into two parts. The first part is to understand the relaxation mechanism in a single molecule and calculate the relevant rate. The second part is to insert this rate into whatever theory (for example, the kinetic equations) governs the dynamics of dipole-coupled molecules, and thus understand the behaviour of the bulk solid. These two parts are logically separate and entail rather different ideas. The first part is entirely quantum mechanical, while the second is entirely classical.

The purpose of the present paper is to address the first part. A calculation of phonoemissive tunneling was in fact done in 1995 [20], and again by one of us more recently [21]. The calculations are similar in spirit, but both are approximate. Further, the first one is done for a tetragonal spin anisotropy in the plane perpendicular to the primary (Ising) anisotropy axis, while the second one is done for biaxial anisotropy. Our goal is to improve upon these calculations (especially the second), since one of the conclusions reached there was that the rate obtained was much too small to account for the experimental observations. It is difficult to devise a simple expression for the error involved and so we revisit the problem, making fewer approximations, and also trying to develop more than one method of calculation.

To explain more fully what we intend to do, let us consider the case of the Fe$_8$ molecule. Neglecting interaction with all other degrees of freedom, the dynamics of the total spin of the molecule, $\mathcal{J}$, are governed by the effective Hamiltonian

$$
\mathcal{H}^\text{e} = -D \mathcal{J}_z^2 + E(\mathcal{J}_x^2 - \mathcal{J}_y^2) + C(\mathcal{J}_+^4 + \mathcal{J}_-^4) - g\mu_B H \cdot \mathcal{J}.
$$

(1.1)
Here, $\mathbf{J}$ is the dimensionless spin angular momentum operator, $\mathbf{H}$ is the external magnetic field, and $C$, $D$, and $E$ are anisotropy energies with $D > E \gg |C| > 0$. The $g$-factor, $g$, is very close to 2, indicating an all-spin magnetic moment, and the magnitude of the total spin, $j$, is 10 as already mentioned. The experimentally deduced values of $D$, $E$, and $C$ are 0.292, 0.046, and $2.9 \times 10^{-5}$ K, respectively. Hence the molecule has an easy axis along $\hat{z}$ and hard axis along $\hat{x}$. The spin-phonon interaction can be very generically written as

$$\mathcal{H}^{\text{sp}} = \sum_{\mu} (F_{\mu}(\mathbf{J}) a_{\mu} + F_{\mu}^\dagger(\mathbf{J}) a_{\mu}^\dagger), \quad (1.2)$$

where $a_{\mu}^\dagger$ and $a_{\mu}$ are phonon creation and annihilation operators for mode $\mu$, and $F_{\mu}(\mathbf{J})$ and $F_{\mu}^\dagger(\mathbf{J})$ are functions of $\mathbf{J}$ that have nonzero matrix elements with $\Delta m = 1$ and $\Delta m = 2$. The phonons themselves are adequately treated in the harmonic approximation, i.e., with a Hamiltonian

$$\mathcal{H}^{\text{p}} = \sum_{\mu} \hbar \omega_{\mu} a_{\mu}^\dagger a_{\mu}. \quad (1.3)$$

Let us first consider the single molecule magnet on its own, and restrict $\mathbf{H}$ to the $x$ axis. Because the anisotropy ratios $E/D$ and $C/D$ are small, it is reasonable to think of these terms, as well as the $H_x$ term, as perturbations, and work in the $J_z$ basis. The two lowest spin states, $m = -j$ and $m = j$ (where $m$ is the quantum number of $J_z$), are then in resonance, and will be split by quantum tunneling. One way to think of this tunneling is that it is caused by the three perturbing terms: $J_x$ connects states with $\Delta m = \pm 1$, $J_x^2 - J_y^2$ connects states with $\Delta m = \pm 2$, and $J_+^4 + J_-^4$ connects states with $\Delta m = \pm 4$. Various combinations of these three terms acting in sequence then connect the $m = -j$ and $m = j$ states with each other, and split their degeneracy, i.e., give rise to tunneling. This method can be used for quantitative calculations of tunnel splittings $[22-25]$, and can even give accurate results $[26]$ for the locations of the diabolical points where the splitting vanishes $[3, 27]$.

The same idea can be applied to find the matrix element for phonoemissive tunneling. Let us take $H_z > 0$ so that the $m = 10$ state is lower in energy than the $m = -10$ state.
For the initial and final states, $|i\rangle$ and $|f\rangle$, let us take

\begin{align*}
|i\rangle &= |m = -10, \text{ no phonons}\rangle, \\
|f\rangle &= |m = 10, \text{ one phonon in mode } \mu(f)\rangle.
\end{align*}

(1.4)

We then consider as perturbations all possible strings of the $H_x$, $E$, and $C$ terms plus the spin-phonon interaction $\mathcal{H}^{sp}$ that take us from $|i\rangle$ to $|f\rangle$, with the restriction that the $m$ quantum number is always increasing. The various strings, as well as the matrix elements of the associated spin operators, and the energy denominators, are easily enumerated and calculated by symbolic manipulation programs. If the resulting matrix element is denoted by $F_{fi}$, the rate or probability of transition per unit time is given by Fermi’s golden rule as

$$\Gamma = \frac{2\pi}{\hbar} \sum_{f} |F_{fi}|^2 \delta(E_f - E_i),$$

(1.5)

where $E_i$ and $E_f$ give the energy of the magnetic molecule plus the phonons in the initial and final states. It is of course the fact that the phonons have a continuum of energies that makes it possible to satisfy the delta function, and thus obtain a nonzero transition rate.

We carry out this perturbative calculation in Sec. III, with a generalization to nonzero temperature, and including the case of absorption. The spin-phonon Hamiltonian and the phonon spectrum are discussed in more detail in this section.

In Sec. IV we perform instead a semiclassical calculation based on spin coherent state path integrals. This method has been very successfully applied to pure spin tunneling, but the application to an inelastic process involving spin is completely novel as far as we know, and quite distinct from the classic calculations of dissipative tunneling involving a continuous position-like degree of freedom \cite{28} in that for our problem tunneling would simply not take place without the mechanism for inelasticity or dissipation. The path integral method is more compact than the perturbative calculation, requires less numerical work, and yields a closed form answer in special cases. Finally, these two approaches provides checks on each other.

The plan of the paper is as follows. In the next section we describe our theoretical model and some general features of the phonoemissive and absorptive rates. Secs. III and IV contain the perturbative and semiclassical calculations. We apply the results of
these calculations to Fe₈ in Sec. V, and briefly discuss the implications of our findings for the magnetization problem described at the beginning of this section, leaving a detailed examination of the issue for a later publication. Finally, technical aspects of the calculations are explained in two appendices.

II. GENERAL ASPECTS OF THE PROBLEM

A. The minimal theoretical model

If the magnetic molecule were truly isolated, and $H_z$ were zero, there would, as discussed in Sec. I, be a tunnel splitting $\Delta$ between the two levels $m = \pm j$, and a state initially localized along one of the directions of classical minima, say $m = -j$, would coherently flip-flop between $m = -j$ and $m = +j$, much like the inversion resonance in NH₃. It is this tunnel splitting that is measured in Ref. [3], although the transitions between the two levels are strongly incoherent in the real system, and there is no flip-flop. Instead, one-shot transitions are induced by means of the Landau-Zener-Stückelberg protocol, and the underlying matrix element is deduced from the rate of relaxation of the net magnetization.

When $H_z$ is small but non-zero, there will be a relative bias $\varepsilon$ between the $+j$ and $-j$ state, given by,

$$\varepsilon = E_{+j} - E_{-j} = -2 j g \mu H_z. \quad (2.1)$$

The two level description between $-j$ and $+j$ is still accurate (provided that $H_z$ is not so large as to trigger the next resonance, say between $m = -j$ and $m = j - 1$), and an isolated molecule would still exhibit coherent oscillations with effective splitting $(\Delta^2 + \varepsilon^2)^{1/2}$. In the real solid, interactions with other degrees of freedom destroy the coherence, and then, as discussed in Sec. I, transitions are in fact not possible for $\varepsilon \neq 0$ unless some environment soaks up or provides the energy $\varepsilon$. When there is a suitable environment, and the coupling to it is sufficiently strong, the transitions turn from flip-flop to incoherent, with a probability that grows linearly with time. The coefficient of this growth is the rate that we seek.

In this paper, we shall take the spin Hamiltonian to be Eq. (1.1), and restrict $H$ to lie in the $xz$ plane. Since the interesting bias energies are of order 1 K, we need only consider long wavelength acoustic phonons. The mode label $\mu$ then consists of the wavevector $k$ and a polarization index $s \in \{1, 2, 3\}$. We now need the spin-phonon interaction more explicitly
than Eq. (1.2). The desired form can be obtained by promoting the classical magnetoelastic interaction [29] to an operator, and takes the form

\[ \mathcal{H}^{sp} = \frac{1}{2} \sum_{a,b,c,d=x}^{z} \Lambda_{abcd} (\partial_{a} u_{b}(0) + \partial_{b} u_{a}(0)) \{\mathcal{J}_{c}, \mathcal{J}_{d}\}, \tag{2.2} \]

where \( \Lambda_{abcd} \) is the magnetoelastic tensor, \( \{\cdot, \cdot\} \) denotes the anticommutator, and \( u \) is the material displacement field of the solid. The prime on the sum indicates the omission of certain terms from it, as we shall explain below. Since we are limiting ourselves to acoustic phonons only, the field \( u(x) \) is given by [30]

\[ u(x) = \sum_{\mu} \sqrt{\frac{\hbar}{2m\omega_{\mu}N}} e^{i\mathbf{k}_{\mu} \cdot \mathbf{x}} (a_{\mu} e^{i\mathbf{e}_{\mu} \cdot \mathbf{x}} + a_{\mu}^\dagger e^{-i\mathbf{e}_{\mu} \cdot \mathbf{x}}), \tag{2.3} \]

where \( m \) is the mass per unit cell of the lattice, \( N \) is the number of unit cells in the solid, \( a_{\mu}^\dagger \) and \( a_{\mu} \) are creation and annihilation operators for phonons of mode \( \mu \), and \( \mathbf{k}_{\mu} \) and \( \mathbf{e}_{\mu} \) are the wavevector and polarization of that mode. The tensor components \( \Lambda_{abcd} \) are not well known, so as a simplification we set [31]

\[ \Lambda_{abcd} = \frac{1}{2} \Lambda (\delta_{ac}\delta_{bd} + \delta_{ad}\delta_{bc}). \tag{2.4} \]

It is useful at this point to note that \( \Lambda \) has dimensions of energy, and that its order of magnitude is expected to be comparable to \( D \). With all the above simplifications, we get

\[ \mathcal{H}^{sp} = i \sum_{\mu} \lambda_{\mu} (a_{\mu} - a_{\mu}^\dagger) \sum_{a,b=x}^{z} (\hat{k}_{a} e_{b}^{\mu} + \hat{k}_{b} e_{a}^{\mu}) \times \frac{1}{2} \{\mathcal{J}_{a}, \mathcal{J}_{b}\}, \tag{2.5} \]

where \( \hat{k}_{\mu} = k_{\mu} / k \), and we have introduced

\[ \lambda_{\mu} = \Lambda k \sqrt{\frac{\hbar}{2m\omega_{\mu}N}} \tag{2.6} \]

to save writing. This quantity has dimensions of energy.

The phonon spectra for single molecule magnets are also not well known in general. But since only the low frequency acoustic modes are of any relevance to us, in the same spirit
that led us to simplify $\Lambda_{abcd}$, we take the phonons to be those of an isotropic continuous medium. That is, we take them to be exactly longitudinal (L) and transverse (T) with the two transverse modes being degenerate for all directions of $k$, and to have a linear dispersion,

$$\omega_L = c_L k, \quad \omega_T = c_T |k|,$$  

(2.7)

with $c_L$ and $c_T$ being the corresponding sound speeds. The sum over all phonon modes can be replaced by an integral in the usual way,

$$\frac{1}{mN} \sum_{\mu} \rightarrow \frac{1}{8\pi^2 \rho} \sum_s \int_0^\infty k^2 dk \int_{S^2} d^2 \hat{k}.$$

(2.8)

Here, $\rho$ is the (mass) density of the material, $d^2 \hat{k}$ denotes an integral over all directions $\hat{k}$, and $s$ labels the polarizations (one longitudinal and two transverse).

As mentioned above, we omit certain terms from the sum in Eq. (2.2). Here is why. The $m = \pm j$ states of the molecule are long-lived, and may be regarded as leading to quasi-equilibrium states of the solid as a whole. In particular, the solid should have no strain in these states. This requirement, along with the linearity of $H^{sp}$ in the strain, implies that $\langle j|H^{sp}|j\rangle$ and $\langle -j|H^{sp}| -j\rangle$ should vanish. The simplest way to ensure this is to omit the terms proportional to $J_z^2$. The alternative would be to project out just the $m = \pm j$ states, but the projection operator that achieves this is a high order polynomial in the components of $\mathbf{J}$, and very difficult to work with. We believe that the differences between the two approaches are physically insignificant, so we adopt the simpler one. Yet another alternative would be to keep the $J_z^2$ terms but for purposes of calculating $\Gamma$, take the initial state of the lattice to be the strained one that results when the molecule is held fixed in the $m = j$ or $m = -j$ state by an external agency. This approach also leads to a calculation that is harder but insignificantly different in its physical implications from the ones that we perform.

B. Interrelationships among various rates

The type of question we wish to now calculate is the following. Suppose the spin is initially in the state $m = -j$, and the phonons are at a temperature $T$. What is the probability that
after a time \( t \), the spin will be in the state \( m = j \) irrespective of the state of the phonons? This (inclusive) probability is given by

\[
P_{-j \rightarrow j}(t) = \sum_{\{n\}_i} \sum_{\{n\}_f} \frac{1}{Z_{\text{ph}}} \exp(-\beta E_{\{n\}_i}^{\text{ph}}) |\langle \{n\}_f, j | \exp(-it\mathcal{H}/\hbar) |\{n\}_i, -j \rangle|^2, \tag{2.9}
\]

where \( \{n\}_i \) and \( \{n\}_f \) are the initial and final phonon configurations, \( E_{\{n\}_i}^{\text{ph}} \) is the energy of the initial phonons, \( \beta = 1/k_B T \), and \( Z_{\text{ph}} \) is the phonon partition function. Under the conditions discussed in Sec. I, except for very small \( t \), this probability can be described in terms of a transition rate, \( \Gamma_{-j \rightarrow j} \). That is,

\[
P_{-j \rightarrow j} = \Gamma_{-j \rightarrow j}(\mathbf{H}, T) t, \tag{2.10}
\]

and we have indicated that the rate depends on the field \( \mathbf{H} \) and the temperature. Under these same conditions, the rates for this transition and its reverse are related by *detailed balance*, that is,

\[
\Gamma_{j \rightarrow -j}(\mathbf{H}, T) = e^{\beta \varepsilon} \Gamma_{j \rightarrow -j}(\mathbf{H}, T), \tag{2.11}
\]

where the bias \( \varepsilon \) is defined by Eq. (2.1). The content of Eq. (2.11) is better stated in words. It says that the ratio of the two rates is given by a Boltzmann factor equal to the ratio of the probabilities of occurrence of the initial states in the Gibbs ensemble. In the mathematical form (2.11) this content is all buried in plus and minus signs. When \( H_z > 0 \), the bias \( \varepsilon < 0 \), the rate on the left side involves phonon absorption, and that on the right involves phonon emission. When \( H_z < 0 \), the bias \( \varepsilon > 0 \), and the left and right sides of the equation pertain to phonon emission and absorption respectively. In all cases, the rate for phonon absorption is \( e^{-\beta|\varepsilon|} \) times that of emission.

While the property of detailed balance follows from very general considerations, we shall also see it explicitly in our calculations in Secs. III. We dwell on this point because the transition rates accompanied by energy transfer to or from the nuclear spins [12, 13] *violate* detailed balance. Formally, this is because the nuclear spins are taken to be “hot,” or completely disordered. They are at effectively infinite temperature, so any factor such as \( e^{\beta \varepsilon} \) is equal to unity.

Let us now try to extract various factors on which these rates must depend as generally as
possible. First, the relation (2.11) guarantees that their absolute temperature dependence is given by the Bose occupation factors,

$$\Gamma_{\pm j \to \mp j}(H, T) \propto \pm \frac{1}{e^{\pm \beta |\varepsilon|} - 1},$$

(2.12)
or, more explicitly, \((1 - e^{-\beta |\varepsilon|})^{-1}\) for emission, and \((e^{\beta |\varepsilon|} - 1)^{-1}\) for absorption. As \(T \to 0\), these factors tend to 1 and 0, respectively. Second, they must be proportional to the energy density of phonons (in the initial state for emission, the final state for absorption) that can participate in the process, i.e., at the energy \(|\varepsilon|\). This consideration gives an additional factor of \(|\varepsilon|^3\). Third, to lowest order in the spin-phonon interaction, the rates must be proportional to \(\Lambda^2\). The remaining dependence on the elastic properties of the solid can arise only via the parameters \(\rho\) and \(c\), the density and speed of sound, and dimensional analysis then shows that it can only take the form

$$\Gamma \sim \frac{\Lambda^2}{\rho \hbar^4 c^5} \times \frac{\pm |\varepsilon|^3}{e^{\pm \beta |\varepsilon|} - 1} \times G,$$

(2.13)
where \(G\) is a dimensionless quantity that depends on \(H_x, H_z\), and the anisotropy ratios \(E/D\) and \(C/D\). This general form may be seen in either Ref. [20] or Ref. [21]. More precisely, we must replace the schematic factor \(G/c^5\) by a weighted average over the longitudinal and transverse modes, which the detailed calculations of the next two sections reveal to be of the form

$$\frac{2G_L}{5c_L^5} + \frac{3G_T}{5c_T^5}.$$

(2.14)
We will choose the numerical factors so that final answer for \(\Gamma\) is written as

$$\Gamma = \frac{\Lambda^2}{2\pi \rho \hbar^4} \times \frac{\pm |\varepsilon|^3}{e^{\pm \beta |\varepsilon|} - 1} \times \left( \frac{G_L}{15c_L^5} + \frac{G_T}{10c_T^5} \right).$$

(2.15)
To be absolutely explicit, let us add to \(\Gamma\), superscripts \(\text{“abs”}\) and \(\text{“em”}\) to indicate absorption and emission, and subscripts \(-j \to j\) or \(j \to -j\) to show the direction of transition, and let corresponding suffixes be added to the \(G\)’s. There are four different \(\Gamma\)’s to be considered, which obey various relationships, better expressed in terms of the \(G\)’s. Two of these are just
reexpressions of detailed balance:

\[
G_{-j\rightarrow +j}(\varepsilon) = G_{+j\rightarrow -j}^{\text{em}}(\varepsilon), \quad G_{+j\rightarrow -j}(\varepsilon) = G_{-j\rightarrow +j}^{\text{em}}(\varepsilon). \tag{2.16}
\]

The other relationships are

\[
G_{-j\rightarrow +j}^{\text{abs}}(\varepsilon) = G_{+j\rightarrow -j}^{\text{abs}}(-\varepsilon), \quad G_{+j\rightarrow -j}^{\text{abs}}(\varepsilon) = G_{-j\rightarrow +j}^{\text{abs}}(-\varepsilon). \tag{2.17}
\]

It must be remembered that these relations hold separately for \(G_L\) and \(G_T\). It follows from Eq. (2.17) that,

\[
\Gamma_{-j\rightarrow j}^{\text{abs/em}}(\varepsilon) = \Gamma_{j\rightarrow -j}^{\text{abs/em}}(-\varepsilon), \tag{2.18}
\]

which is an expression of time-reversal symmetry combined with a 180° rotation about the z axis, i.e., the invariance of the system under \(m \rightarrow -m\) and \(H_z \rightarrow -H_z\).

A very similar argument shows that the \(\Delta m = 1\) and \(\Delta m = 2\) amplitudes will be odd and even functions respectively of \(H_z\) if \(j\) is an integer, and the other way around if \(j\) is a half-integer. This property is a useful calculational check.

There is one more property of the rates that may be described as a symmetry. Every rate ends up being a sum of two subrates, one involving spin-phonon processes with \(\Delta m = 1\), and the other involving \(\Delta m = 2\). That this is so, and that there is no interference between these two alternatives is because our spin-phonon interaction is invariant under all rotations, not just the restricted rotations in the point group that would be relevant for a real solid. Angular momentum is thus fully conserved, and so in principle we can distinguish tunneling that required the \(\Delta m = 1\) vs. the \(\Delta m = 2\) part of \(\mathcal{H}^{\text{sp}}\) by looking at the angular momentum carried by the emitted or absorbed phonon. Since the remaining change in \(m\) (19 or 18) must then be due to the action of the spin Hamiltonian \(\mathcal{H}^s\) alone, the corresponding amplitudes must be odd and even in \(H_z\), respectively. (The subrates themselves are of course always even, but this fact is another useful check on the calculations.) This point is perhaps clearer in the context of the calculations themselves, but it is worth noting here also. Naturally, this property will not hold strictly for a real system, but it may still be approximately true.

Because of all these symmetries, we need only give four quantities (\(G_L\) and \(G_T\), each for \(\Delta m = 1\) and \(\Delta m = 2\)) for anyone of the four rates. The corresponding quantities for the rates then follow from the symmetry relations, and there is no need to give them separately.
For our standard process, we shall take $-j \to j$ phonoemission, and give the $G's$ for it. Further, to avoid cluttering the formulas, we shall omit the distinguishing suffixes wherever we can do so without creating ambiguity. Thermostatistical factors such as $\varepsilon^3/(1 - e^{-\beta\varepsilon})$, as well as the dimensional factors involving $\Lambda^2$ and the sound speeds can be incorporated for any other process as needed.

III. PERTURBATION THEORY

The evaluation of $P_{-j\to j}$ [see Eq. (2.9)] requires a generalization of the second-order Fermi golden rule [32], which is achieved as follows. We divide the total Hamiltonian for the molecule and the phonons into two parts, $\mathcal{H}_0$, and $V$, where

$$\mathcal{H}_0 = -D\mathcal{J}_z^2 - g\mu_B H_z \mathcal{J}_z + \mathcal{H}^p, \quad (3.1)$$

and

$$V = \mathcal{H}_1 + \mathcal{H}_2 + \mathcal{H}_4 + \mathcal{H}^{sp}, \quad (3.2)$$

with

$$\mathcal{H}_1 = -g\mu B J_x, \quad \mathcal{H}_2 = E(\mathcal{J}_x^2 - \mathcal{J}_y^2), \quad \mathcal{H}_4 = C(\mathcal{J}_+^4 + \mathcal{J}_-^4). \quad (3.3)$$

The usual perturbative expansion gives us

$$e^{-i\mathcal{H}t/\hbar} = 1 + \frac{1}{i\hbar} \int_0^t dt_1 V(t_1) + \frac{1}{(i\hbar)^2} \int_0^t dt_1 \int_0^{t_1} dt_2 V(t_1)V(t_2) + \cdots, \quad (3.4)$$

with $V(t)$ being the perturbation in the interaction picture. We must take the matrix element of this operator between the initial and final states, which we simplify as follows. First, our final state differs from the initial one by $\Delta m = 2j$, which is 20 for Fe$_8$. To get such a large change in $m$, one must go to an order such that there are sufficiently many interaction terms $V(t_i)$. There are many ways to achieve this. For example, in sixth order, we could select the following sequences of terms:

$$\mathcal{H}_4(t_6), \mathcal{H}_4(t_5), \mathcal{H}_2(t_4), \mathcal{H}_4(t_3), \mathcal{H}^{sp}(t_2), \mathcal{H}_2(t_1); \quad (3.5)$$
and in seventh order we could select

\[ \mathcal{H}_2(t_7), \mathcal{H}^{\text{op}}(t_6), \mathcal{H}_4(t_5), \mathcal{H}_4(t_4), \mathcal{H}_4(t_3), \mathcal{H}_4(t_2), \mathcal{H}_1(t_1). \] (3.6)

It is evident that each sequence can be considered to correspond to a discrete path in the space of Zeeman states. All possible paths must be considered, and their contribution to the transition matrix element must be added together. To make the calculation tractable, we make the following simplifications. First, we can divide the paths into different types of classes characterized by how many times each one of the four parts of \( V(t) \) appears. We demand that all classes must be considered subject to the constraint that the \( m \) quantum number must be strictly increasing (or strictly decreasing for the \( j \to -j \) transition). Thus the sequence

\[ \mathcal{H}_2(t_8), \mathcal{H}_2(t_7), \mathcal{H}^{\text{op}}(t_6), \mathcal{H}_4(t_5), \mathcal{H}_4(t_4), \mathcal{H}_4(t_3), \mathcal{H}_4(t_2), \mathcal{H}_1(t_1), \] (3.7)

will be ignored since when we compare it with (3.6), it is seen to require a step in which \( m \) decreases \[33\]. Second, we demand that in each path, \( \mathcal{H}^{\text{op}} \) appear once and only once. If it does not appear at all, we can not allow for energy conservation if there is a significant bias, and so the path in question cannot contribute to the incoherent transition rate. (It is instead, part of the contribution to \( \Delta \), the coherent flip-flop tunnel splitting.) And, we limit it to only one appearance because \( \Lambda \) is small, so it suffices to work to lowest order in \( \Lambda \). This is another way of saying that we limit ourselves to one-phonon processes. In the transition matrix element, therefore, we need only display the phonon occupation number of the mode that is affected, and the transition probability simplifies to

\[
\mathcal{P}_{\text{one-phonon}}^{-j \to j} = \sum_{\mu} \sum_{n_\mu} \frac{e^{-\beta \omega_\mu n_\mu}}{2^{\text{ph}}_\mu} |\langle n_\mu + 1, j | \exp\{-it\mathcal{H}/\hbar\} \rangle |n_\mu, -j|^2 \\
+ \sum_{\mu} \sum_{n_\mu} \frac{e^{-\beta \omega_\mu n_\mu}}{2^{\text{ph}}_\mu} |\langle n_\mu - 1, j | \exp\{-it\mathcal{H}/\hbar\} \rangle |n_\mu, -j|^2,
\]

(3.8)

where we have explicitly separated the phonoemissive and phonoabsorptive processes, and it is understood that we employ the perturbation expansion (3.4) with the simplifications already mentioned.
We now note that since $\mathcal{H}\text{sp}$ is to appear only once in the expansion of $e^{-i\mathcal{H}t/\hbar}$, the phonon part of the transition matrix element is always

$$\langle n_\mu + 1|a_\mu^\dagger|n_\mu \rangle = \sqrt{n_\mu + 1}, \quad \text{or} \quad \langle n_\mu - 1|a_\mu|n_\mu \rangle = \sqrt{n_\mu},$$

(3.9)

for emission and absorption respectively. Summing over the Boltzmann weight then gives precisely the Bose thermal occupation numbers $\langle n_\mu + 1 \rangle = (1 - \exp\{-\beta\hbar\omega_\mu\})^{-1}$ and $\langle n_\mu \rangle = (\exp\{\beta\hbar\omega_\mu\} - 1)^{-1}$ for these two processes, and their rates are guaranteed to obey detailed balance. Henceforth we consider only $-j \to j$ phonoemission; this implies that $\varepsilon < 0$. We also omit the Bose factors which can be restored at the end. Formally this is like working at $T = 0$.

The remaining $V(t_i)$ and $\mathcal{H}\text{sp}$ in any path give rise to a number of factors of the form $e^{-i(E_k - E_\ell)t_i}$, where $E_k$ and $E_\ell$ are the energies of intermediate states along the path. When we integrate over all the $t_i$, all but one of these integrations will generate energy denominators of the form $(E_k - E_i)$, and the remaining one will generate an overall sinc function which upon squaring can be replaced by $t\delta(E_f - E_i)$ by standard arguments \[32\]. The upshot is that

$$\mathcal{P}_{-j \to j}^{\text{em}} = \Gamma_{-j \to j}^{\text{em}} t,$$

(3.10)

where

$$\Gamma_{-j \to j}^{\text{em}} = \frac{2\pi}{\hbar} \sum_\mu \delta(\varepsilon + \hbar\omega_\mu)|\mathcal{F}_{-j \to j}^\mu|^{2}. \quad (3.11)$$

The quantity $\mathcal{F}$ (suppressing the suffixes) is a transition matrix element with the following structure:

$$\mathcal{F} = \sum \frac{\langle f|V|s_{n-1}\rangle \langle s_{n-1}|V|s_n \rangle \cdots \langle s_1|V|i \rangle}{(E_i - E_{n-1})(E_i - E_{n-2})\cdots(E_i - E_1)}. \quad (3.12)$$

Here the $s_k$’s denote intermediate states, with energies $E_k$ (which include the energies of the phonons), the $V$’s are the interactions in the usual Schrödinger picture (which are time independent), and the sum is over all paths from $-j$ to $j$ with the restrictions mentioned above. For the numerator, we note that since $m$ is always increasing along a path, the product of spin matrix elements will always contain the factor

$$\langle j|\mathcal{F}_{+j}^{2j}|-j \rangle = (2j)!. \quad (3.13)$$
In the denominator, the energies $E_k$ include those of the phonons.

The problem of calculating $\mathcal{F}$ thus reduces to enumerating all the (restricted) paths, multiplying the correct number of relevant couplings, $E$, $C$, and $H_x$ in the numerator (there is always one factor of $\Lambda$), the energy differences in the denominator, and then summing over paths. This task is easily automated to a computer, but before doing that it is worth simplifying it further by anticipating the structure of the sum over phonon modes. Let us define

$$Q_{ab} = \frac{1}{2} \{J_a, J_b\}. \tag{3.14}$$

There are six such operators in all, but as explained in Sec. II A, $H^{sp}$ does not contain $Q_{zz}$. Even if such a term were present in $H^{sp}$, however, it would lead to $\Delta m = 0$ processes, so we would discard it in accord with the requirement that $m$ be strictly increasing along a path. For the same reason, we can make the following replacements for the $\Delta m = 2$ operators:

$$Q_{xx} \to \frac{J^2_+}{4}, \quad Q_{xy} \to -i\frac{J^2_+}{4}, \quad Q_{yy} \to -\frac{J^2_+}{4}. \tag{3.15}$$

(We show the replacements for the $-j$ to $j$ rate; for $j$ to $-j$, we simply use the Hermitean conjugates.) Further, since the $J^2_+$ operator is incorporated in the common factor (3.13), we need only keep track of the numerical factors of $1/4$, $-i/4$, and $-1/4$. Matters are slightly more involved for the $\Delta m = 1$ operators. This time, we have to keep track of where in the $-j$ to $j$ chain they act. It is easy to see that the replacement rule is

$$\langle m + 1|Q_{xz}|m\rangle \to \frac{1}{2}(m + \frac{1}{2}), \quad \langle m + 1|Q_{yz}|m\rangle \to -\frac{i}{2}(m + \frac{1}{2}), \tag{3.16}$$

the $J_+$ part being already absorbed in the factor (3.13). In fact, if we change the common factor to

$$\langle j|(\frac{1}{2}J_+)^{2j}| - j\rangle = \frac{(2j)!}{2^{2j}}, \tag{3.17}$$

we can use the simpler replacement rules

$$(Q_{xx}, Q_{xy}, Q_{yy}, Q_{xz}, Q_{yz}) \to (1, -i, -1, (m + \frac{1}{2}), -i(m + \frac{1}{2})). \tag{3.18}$$

It follows that we can split $\mathcal{F}$ into two sums, corresponding to the value of $\Delta m$ carried
by $\mathcal{H}^{\text{sp}}$. In other words, we may write,

$$
\mathcal{F}^{ks} = -i\lambda_{ks} \left[ \hat{k}_- e_-^{ks} M_2(\omega_{ks}) + (\hat{k}_- e_z^{ks} + \hat{k}_z e_-^{ks}) M_1(\omega_{ks}) \right],
$$

(3.19)

where,

$$
\hat{k}_\pm = \hat{k}_x \pm i\hat{k}_y, \quad e_\pm = e_x^{ks} \pm ie_y^{ks},
$$

(3.20)

and $M_m(\omega_{ks})$ is the rest of the matrix element, with the subscript showing the value of $\Delta m$.

This matrix element is dimensionless because we have factored out $\lambda_{ks}$. We have written out the phonon mode index $\mu$ more fully to show that it consists of the wavevector $k$ and polarization label $s$. For $m = 2$, the matrix elements $M_m$ that remain at this stage have the structure

$$
M_2 = 2 \frac{(2j)!}{2^{2j}} \sum_{\text{paths}} \text{product of coupling constants} \text{ product of energy denominators},
$$

(3.21)

where the additional factor of 2 arises from the symmetry of the tensor $(\hat{k}_a^\mu e_b^\mu + \hat{k}_b^\mu e_a^\mu)$, the “coupling constants” are $-g\mu_B H_x$, $2E$, and $16C$. Note that the coupling constant $\lambda_{ks}$ from $\mathcal{H}^{\text{sp}}$ has already been removed from the numerator. For $M_1$, there is an additional factor of $(m + \frac{1}{2})$ in the numerator, where $m$ depends on where in the path $\mathcal{H}^{\text{sp}}$ acts.

As part of the sum over all phonon modes, we must sum over the three polarizations, and integrate over the directions of $k$. We show how this is done in Appendix A. The result has two contributions, one from the longitudinal modes, and the other from the two transverse modes taken together. We may write this as

$$
\int d^2\hat{k} \sum_s |\mathcal{F}^{ks}|^2 = F_L(k) + F_T(k),
$$

(3.22)

where

$$
F_\alpha(k) = \frac{16\pi}{15} |\lambda_{ka}|^2 \left[ |M_1(c_\alpha k)|^2 + |M_2(c_\alpha k)|^2 \right] \times \begin{cases} 2, & \alpha = L, \\ 3, & \alpha = T. \end{cases}
$$

(3.23)

It remains to integrate over the magnitude of the phonon wavevector. When this is done, we obtain

$$
\Gamma_{n\rightarrow j}^{\text{em}} = \frac{4\Lambda^2}{\pi \rho \hbar^2} \left( \frac{1}{15c_L^2} + \frac{1}{10c_T^2} \right) |\varepsilon|^3 \left( |M_{1,n\rightarrow j}^{\text{em}}|^2 + |M_{2,n\rightarrow j}^{\text{em}}|^2 \right),
$$

(3.24)

where the suffixes on the $M$’s now indicate the value of $\Delta m$ as well as the transition involved.
more fully. Note that the $M$’s are functions of the spin anisotropies, $D$, $C$, and $E$, the external field $H_x$, and the bias $\varepsilon$ (as a proxy for $H_z$). In terms of the quantities $G_L$ and $G_T$ introduced in Sec. II B, Eq. (3.24) means that

$$G_{pt}^L = G_{pt}^T = 8 \left[ |M_{1,-j\rightarrow j}^{em}|^2 + |M_{2,-j\rightarrow j}^{em}|^2 \right], \quad (3.25)$$

where the superscript ‘pt’ stands for ‘perturbation theory,’ and we may refer to both $G_L^{pt}$ and $G_T^{pt}$ by just one name, $G^{pt}$, because of their equality. The power of five to which the speeds of sound occur is a major source of uncertainty for the transition rate; and since $c_T$ is typically half of $c_L$, the transverse contribution is likely to dominate.

Before moving onto the semiclassical calculation, let us see how the general consequences of time-reversal symmetry that were mentioned in Sec. II B play out in the above calculation. Under the transformation $m \rightarrow -m$ and $H_z \rightarrow -H_z$, the energy denominators remain unchanged, while for the numerators, those for paths containing a phonon-coupling term with $\Delta m = \pm 1$ will change sign, but those with $\Delta m = \pm 2$ will not. As a result,

$$M_{1,-j\rightarrow j}^{em}(\varepsilon) = -M_{1,-j\rightarrow j}^{em}(-\varepsilon), \quad M_{2,-j\rightarrow j}^{em}(\varepsilon) = M_{2,-j\rightarrow j}^{em}(-\varepsilon). \quad (3.26)$$

After taking the squared absolute values, the minus sign in the $M_1$ relation is immaterial, so Eq. (2.18) follows. Furthermore we see that $M_1(0) = 0$ due to this antisymmetry.

In the same vein, we look at $M_1$ and $M_2$ as a function of $H_x$. When $j$ is an integer the transition from $-j$ to $+j$ (and vice versa) must take an even number of steps in $m$. Since both $H_2$ and $H_4$ have even $\Delta m$, the remaining combination of $H_1$ (through which the external field $H_x$ appears) and $Q_{ab}$ must also result in an even $\Delta m$. Therefore, the $M_1$ term, which results from the $\Delta m = 1$ part of $Q_{ab}$, must include an odd number of appearances of $Q_1$, and so must be an odd function of $H_x$. In the same way, the $M_2$ term is an even function of $H_x$. Consequently, at $H_x = 0$ the $M_1$ contribution also vanishes. We shall find the same thing in the semiclassical calculation.

**IV. SEMICLASSICAL INSTANTON CALCULATION**

Our goal in this section is to treat the spin by semiclassical methods, exploiting the fact that in many interesting cases, the spin is large. This is formally a different approximation
from perturbation theory, although when \( j \) is large, the large number of intermediate states leads to a certain similarity. Another reason for the semiclassical approach is that it leads to a compact answer for the rate where the perturbative one does not.

The semiclassical approach we use will be based on spin coherent state path integrals. In order not to interrupt their application to the problem of this paper, we present a brief review of their use in the context of pure spin tunneling, especially for \( \text{Fe}_8 \). We then apply them to the phonoemission and absorption, and then discuss these phenomena in the specific case of \( \text{Fe}_8 \).

### A. Pure spin tunneling via instantons

Let us consider the pure spin (no phonons) tunneling amplitude

\[
U_{fi}(t) = \langle j | \exp(-i\mathcal{H}_0^s t/\hbar) | -j \rangle, \tag{4.1}
\]

where \( \mathcal{H}_0^s \) is the spin Hamiltonian (1.1) with \( H_z = 0 \):

\[
\mathcal{H}_0^s = -D \mathcal{J}_z^2 + E(\mathcal{J}_x^2 - \mathcal{J}_y^2) + C(\mathcal{J}_+^4 + \mathcal{J}_-^4) - g\mu_B H_x \mathcal{J}_x. \tag{4.2}
\]

Since we intend to evaluate it via spin coherent state path integrals, we give our definition of spin coherent states, which is

\[
|\bar{z}\rangle = (1 + z\bar{z})^{-j} \exp\{\bar{z}J_+\}|j, -j\rangle, \quad \langle z| = (1 + z\bar{z})^{-j} \langle j, -j| \exp\{zJ_-\}. \tag{4.3}
\]

Here, \( z \) is a complex number giving the coordinates of the state in the spin phase space \( S^2 \) expressed via stereographic projection as \( \mathbb{C} + \{\infty\} \). As before, an overbar denotes complex conjugation. The preimage of this projection on the unit sphere has the Cartesian components

\[
s_x = \frac{z + \bar{z}}{z\bar{z} + 1}, \quad s_y = \frac{1}{i} \frac{z - \bar{z}}{z\bar{z} + 1}, \quad s_z = \frac{z\bar{z} - 1}{z\bar{z} + 1}. \tag{4.4}
\]

The vector \( \mathbf{s} \) gives the direction in which the spin “points” when it is in the state \( |\bar{z}\rangle \). In particular, the spin state \( m = -j \) corresponds to \( \bar{z} = 0 \) and \( \mathbf{s} = -\hat{z} \), while \( m = +j \) corresponds to the point at infinity and \( \mathbf{s} = \hat{z} \). In the classical limit, the operator \( \mathcal{J} \) has
vanishing relative fluctuation about its mean value, j. We can see this from the matrix elements,

\[ \langle z|J_a|\bar{z}\rangle = js_a(z), \quad \frac{1}{2}\langle z|\{J_a,J_b\}|\bar{z}\rangle = j(j - \frac{1}{2})s_a(z)s_b(z) + \frac{1}{2}j\delta_{ab}. \]  

(4.5)

In what follows, it will help to think of 0 and t as “initial” and “final” times. We therefore define

\[ t_i \equiv 0, \quad t_f \equiv t. \]  

(4.6)

With this relabelling, the path integral expression for \( U_{fi} \) is

\[ U_{fi}(t_f, t_i) = \mathcal{N} \int Dz \exp \left( iS^{\text{spin}}[z]/\hbar \right). \]  

(4.7)

Here, the sum is over all paths that go from \( \bar{z}_i = \bar{z}(t_i) = 0 \) to \( z_f = z(t_f) = \infty \), \( S^{\text{spin}} \) is the semiclassical action for the spin Hamiltonian \( \mathcal{H}_0^s \), and \( \mathcal{N} \) is a normalization constant. (The exact forms of \( \mathcal{N} \) and \( S^{\text{spin}} \) will not be needed; for complete details see [34].) Since \( \mathcal{H}_0^s \) is a matrix of finite order, \( 2j + 1 \), the amplitude \( U_{fi} \) is an entire function of \( t_f \) and \( t_i \), viewing these as complex variables. The instanton method is essentially an infinite-dimensional steepest descent approximation to \( U_{fi} \)’s analytic continuation onto the imaginary time axis,

\[ t_f \to -i\tau_f, \quad t_i \to -i\tau_i. \]  

(4.8)

The instanton is a path, \( z_d(\tau) \), \( \bar{z}_d(\tau) \), or \( s_d(\tau) \) (the subscript d stands for dominant), that obeys the boundary conditions and stationarizes the action \( S^{\text{spin}} \). For example, for the Hamiltonian (4.2) when \( C = 0, H_x = 0 \) [34]

\[ s_d(\tau; q, \tau_c) = iq\sqrt{\frac{D - E}{2E}} \text{sech} \, \Omega(\tau - \tau_c) \hat{x} + q\sqrt{\frac{D + E}{2E}} \text{sech} \, \Omega(\tau - \tau_c) \hat{y} + \tanh \, \Omega(\tau - \tau_c) \hat{z}. \]  

(4.9)

Here, \( \Omega = 2j\sqrt{D^2 - E^2}/\hbar \) is the characteristic instanton frequency. Its inverse is the time scale over which the instanton makes the transition from \( s_d(\tau_i) = -\hat{z} \) to \( s_d(\tau_f) = +\hat{z} \). Strictly speaking, the instanton is only defined for \( \tau_f \to +\infty, \, \tau_i \to -\infty \), but the method may be employed as long as

\[ \tau_f - \tau_i \gg \Omega^{-1}. \]  

(4.10)
Quite generally, $\hbar \Omega$ is comparable to the energy difference between the $m = j$ and $j - 1$ energy levels. Further, $\tau_c$ is the center of the instanton where it switches between its end point values. The arbitrariness in the location of this center arises from the temporal translational invariance of the action, and is a general feature of all instanton solutions.

Finally, there is one feature of Eq. (4.9) that is special to the Hamiltonian (4.2). There is not one, but two instantons, that differ in that they wind about the hard axis in opposite senses, as labelled by the parameter $q = \pm 1$. The (imaginary time, or Euclidean) action for these instantons has the same real part, but different imaginary parts,

$$\frac{1}{\hbar} S[z_d(\tau), \bar{z}_d(\tau)] = I + i q \frac{\Theta}{2}, \tag{4.11}$$

and it is interference between them that is responsible for the experimentally observed diabolical points [3, 27]. If instead we had $E = 0$ and $C \neq 0$, there would be four instantons to consider [26].

Because $\Omega^{-1} \ll \tau_f - \tau_i$, in general one must consider multi-instanton paths. As long as the centers of these instantons are well separated on the $\Omega^{-1}$ time scale, these paths also stationarize the action, and are valid saddle points. For the moment let us consider only one-instanton paths. In this case, the saddle point approximation means that the sum over all paths is replaced by

$$\mathcal{N} \int Dz \to \sum_q \int_{\tau_i}^{\tau_f} d\tau_c \times \mathcal{N} \int D\xi, \tag{4.12}$$

where the path integral is now over small fluctuations around the instanton,

$$\xi(\tau) = z(\tau) - z_d(\tau), \quad \bar{\xi}(\tau) = \bar{z}(\tau) - \bar{z}_d(\tau). \tag{4.13}$$

At the same time, the action is expanded to quadratic order in $\xi, \bar{\xi}$,

$$S_{\text{spin}} = S[z_d, \bar{z}_d] + \delta^2 S(\xi, \bar{\xi}). \tag{4.14}$$

(We write the quadratic term as $\delta^2 S$ because it can be thought of as the second order change in $S$ when the path is varied from $z_d, \bar{z}_d$ to $z_d + \xi, \bar{z}_d + \bar{\xi}$; the first order change vanishes on
account of stationarity.) Hence the transition amplitude is given by
\[
U_{fi} = \sum_q \int_{\tau_i}^{\tau_f} d\tau_c e^{-\left(I+iq\Theta/2\right)/\hbar} \times \mathcal{N} \int \mathcal{D}\xi e^{-\delta^2 S/\hbar}. 
\] (4.15)

The integral over \(\tau_c\) yields a factor of \(\tau_f - \tau_i\). The Gaussian fluctuation integral is equal for both values of \(q\) because of symmetry. Hence, writing
\[
e^{-I} \times \mathcal{N} \int \mathcal{D}\xi e^{-\delta^2 S/\hbar} = \frac{W}{4\hbar}, 
\] (4.16)
and
\[
\Delta = W \cos\left(\frac{1}{2}\Theta\right), 
\] (4.17)
we obtain
\[
U_{fi} = \frac{\Delta}{2\hbar} (\tau_f - \tau_i). 
\] (4.18)

This is the first term in the expansion of \(\sinh(\Delta(\tau_f - \tau_i)/2\hbar)\). Higher order terms are generated by multi-instanton paths \([35]\). Since the structure of this expansion is fairly straightforward, it generally suffices to consider only one-instanton order to see it. The analytic continuation back to the real time axis yields \(\sin(\Delta t/2\hbar)\) for \(U_{fi}\), which is what we expect for a system with two ground states tunnel split by an energy \(\Delta\).

If we now let \(H_x\) become nonzero while keeping \(C = 0\), the above picture holds unchanged, except that \(I\) and \(\Theta\) are functions of \(H_x\). The splitting vanishes whenever \(\Theta\) is an odd multiple of \(\pi\), producing a diabolical point.

Next let us ask what happens if we allow \(C\) to be nonzero. In this case, everything said above continues to be true for \(H_x = 0\) and sufficiently small \(H_x\). There are, however, two new instanton solutions which also stationarize \(S\), but because their action is large, they are physically inconsequential. This ceases to be true once \(H_x\) crosses a certain value (depending on how large \(C\) is). Then, one of the new instantons has the least action, and since it is without an interfering partner, the diabolical points move off the \(H_x\) axis into the \(H_x-H_y\) plane \([36–38]\).

We shall confine our analysis of phonoemissive tunneling to small value of \(H_x\), where the extra \(C \neq 0\) instantons are not important. As far as we are aware, there are no systematic studies of the magnetization process as a function of \(H_x\).
B. Application to phonoemissive tunneling

For the reasons given in Sec. II B, we need calculate only the $-j \rightarrow j$ phonoemissive rate at $T = 0$. Answers for $T \neq 0$ merely require inclusion of Bose occupation factors. We are thus led to consider the one-phonon transition matrix element

\[ A_{fi}^{\mu}(t) = \langle j, n_\mu = 1 | \exp(-i \mathcal{H} t / \hbar) | -j, n_\mu = 0 \rangle. \]  

(4.19)

We evaluate this by treating just $\mathcal{H}^{sp}$ to first order in perturbation theory. Then,

\[ A_{fi}^{\mu}(t) = \frac{1}{i \hbar} \int_0^t dt' \langle j, 1 | \mathcal{H}^{sp}(t') | -j, 0 \rangle, \]  

(4.20)

where $\mathcal{H}^{sp}(t')$ is in the interaction picture. Evaluating the phonon part of this matrix element, we get

\[ A_{fi}^{\mu} = -\frac{\lambda^\mu}{\hbar} \sum_{a,b} (\hat{k}_a^\mu \hat{c}_b^\mu + \hat{k}_b^\mu \hat{c}_a^\mu) \times \int_0^t dt' e^{i \omega_{\mu} t'} \langle j | e^{-i \mathcal{H} (t-t') / \hbar} Q_{ab} e^{-i \mathcal{H} t' / \hbar} | -j \rangle, \]  

(4.21)

where we have discarded the irrelevant overall phase factor $e^{-i \omega_{\mu} t}$. The prime on the sum indicates the $a = b = z$ term is to be excluded.

The remaining matrix element in Eq. (4.21) refers only to the spin. If we express it terms of the spectral representation of $\mathcal{H}^s$, it is an excellent physical approximation to restrict ourselves to the lowest two states. It is then evident that the matrix element is characterized by two very different energy scales, which pertain to very different physical aspects of the problem. The two energy scales are the difference in the energy eigenvalues, and the tunneling amplitude or matrix element. The former can be well approximated by $\varepsilon$ when $\varepsilon \gg \Delta$, a condition which is very easily satisfied. The amplitude for tunneling is not significantly influenced by the bias, and so we may take it as its value at zero bias, $\Delta$. It is further evident that the states with $m = -j$ and $m = j$ have near unit overlap with the higher and lower energy states respectively. Therefore, we may write

\[ \langle j | e^{-i \mathcal{H} (t-t') / \hbar} Q_{ab} e^{-i \mathcal{H} t' / \hbar} | -j \rangle \simeq e^{-i \varepsilon (t-t') / \hbar} T_{ab}(t, t') \]  

(4.22)
where,

\[ T_{ab}(t, t') = \langle j | e^{-i\mathcal{H}_0(t-t')/\hbar} Q_{ab} e^{-i\mathcal{H}_0 t'/\hbar} | -j \rangle. \]  

(4.23)

It follows that

\[ A_{fi}^\mu \simeq -\frac{\lambda^\mu}{\hbar} \sum_{a,b} \left( \hat{k}_a^\mu e_b^\mu + \hat{k}_b^\mu e_a^\mu \right) \int_0^t dt' e^{i(\omega_\mu + \varepsilon/\hbar)t'} T_{ab}(t, t'), \]

(4.24)

where we have discarded another irrelevant overall phase factor, \( e^{-i\varepsilon t/\hbar} \).

The matrix element that remains in Eq. (4.24), \( T_{ab} \), may be said to pertain solely to the tunneling aspects of the problem, and we expect it to be proportional to \( \Delta \) (or \( W \) more generally). This matrix element may also be written as a path integral:

\[ T_{ab}(t_f, t') = N \int Dz e^{iS_{\text{spin}}[z]/\hbar} \langle z(t') | Q_{ab} | \bar{z}(t') \rangle. \]  

(4.25)

Here again, the sum is over all paths that go from \( \bar{z}_i = \bar{z}(t_i) = 0 \) to \( z_f = z(t_f) = \infty \). All other symbols are as in Eq. (4.7), with \( t_i = 0, t_f = t \), in particular.

As we will see below, we shall require \( A_{fi}^\mu(t) \) for \( t \gg \hbar/\varepsilon \). If this condition is met, then, since \( \varepsilon \ll \hbar \Omega \), it is certainly true that \( t \gg \Omega^{-1} \). If we make the analytic continuation to imaginary times, we will have \( \Omega^{-1} \ll \tau_f - \tau_i \), and we may again use our infinite-dimensional steepest descent approximation. To better understand this, let us recall how one uses steepest descents to evaluate a one-dimensional integral such as

\[ J = \int dx \ g(x) e^{-af(x)}. \]  

(4.26)

If the saddle point of \( f(x) \) is located at \( x_0 \), one expands \( f(x) \) and \( g(x) \) about \( x_0 \), and performs the resulting Gaussian integrals to get an asymptotically valid expansion in inverse powers of \( a^{1/2} \). To leading order, we have

\[ J \approx g(x_0) e^{-af(x_0)} \int dx \ e^{-a(x-x_0)^2} f''(x_0)/2 \approx g(x_0) \int dx \ e^{-af(x)}. \]

(4.27)

In the case of the path integral (4.25), the saddle point is the entire instanton path, \( z_d(\tau) \), \( \bar{z}_d(\tau) \). Hence we must evaluate \( \langle z | \{ \mathcal{J}_a, \mathcal{J}_b \} | \bar{z} \rangle \) for \( z(\tau) = z_d(\tau), \bar{z}_d(\tau) \), do the same for \( e^{iS} \), and then integrate over the Gaussian fluctuations. Finally, we must remember to integrate over the location of the instanton center, and sum over the two types of instantons, i.e., the
two windings. Carrying out all these steps, we obtain,

\[ T_{ab}(\tau_f, \tau_i, \tau') = \sum_q \int_{\tau_i}^{\tau_f} d\tau_c e^{-\left(1 + i q\Theta/2\right)/h} C_{ab}(q, \tau_c) \times \mathcal{N} \int D\xi e^{-\delta^2 S/\hbar}, \quad (4.28) \]

where

\[ C_{ab}(q, \tau_c) = |z(\tau') q| Q_{ab} |\bar{z}(\tau') q\rangle, \quad (z(\tau') = z_d(\tau'; q, \tau_c)). \quad (4.29) \]

It should be further noted that in evaluating the matrix element \( C_{ab} \), we retain only the leading order in \( j \) because the rest of the path integral is evaluated to this order only. This means that if we write \( s_d \) for the vector \( s \) along the instanton path,

\[ C_{ab}(q, \tau_c) = j^2 s_{d,a}(\tau' - \tau_c; q) q_{d,b}(\tau' - \tau_c; q). \quad (4.30) \]

We now recall that \( \tau_f > \tau' > \tau_i \). Unless \( \tau' \) is very close to the end points, the \( \tau_c \) integral may be evaluated by pushing its limits to \( \pm\infty \), and when that is done, the result is independent of \( \tau' \). As opposed to the case of \( U_{fi} \), where the \( \tau_c \) integral gave us a factor of \( \tau_f - \tau_i \), here we will obtain just a number for \( T_{ab} \), essentially independent of all time arguments. Using Eq. (4.16) we may write,

\[ T_{ab} = \frac{W}{4\hbar} \sum_q e^{i q\Theta/2} \int_{-\infty}^{\infty} d\tau_c C_{ab}(q, \tau_c). \quad (4.31) \]

Let us comment briefly on the effect of the multi-instanton paths, which we have neglected above. Qualitatively, we would expect these to modify the \( e^{-i\epsilon(t-t')} \) phase factor that we extracted in Eq. (4.22) by taking into account the effects of tunneling. The primary effect would be to modulate the phase factor by an expression that varied at frequencies of order \( \Delta/h \). Within the scope of a Fermi golden rule calculation such a refinement is academic, and we are well justified in ignoring it.

As an example, let us evaluate Eq. (4.31) for \( T_{ab} \) for the specific case of the \( C = 0, H_x = 0 \)
instantons (4.9). The integrals involved are elementary, and to leading order in $j$, we get

$$ T_{ab} = \frac{j^2 \Delta}{2 \hbar \Omega} \times \begin{cases} - (D - E)/E, & a b = x x, \\ i(D^2 - E^2)^{1/2}/E, & a b = x y, \\ (D + E)/E, & a b = y y. \end{cases} \quad (4.32) $$

The components $T_{xz}$ and $T_{yz}$ vanish. More generally, they are odd functions of $H_x$, while the three components given above are even functions. The component $T_{zz}$ is immaterial since the $Q_{zz}$ term is absent in $\mathcal{H}^{sp}$. We expect all components of this tensor to be of order $\Delta/\hbar \Omega$ as a rule just by dimensional arguments.

Returning to our transition amplitude, we have,

$$ A_{fi}^\mu (t) = - \frac{\lambda_\mu}{\hbar} \int_0^t dt' e^{i(\omega_\mu + \varepsilon/\hbar)t'} \sum_{a,b}' (\hat{k}_a^{\mu} e_b^\mu + \hat{k}_b^{\mu} e_a^\mu) T_{ab}. \quad (4.33) $$

The sum is independent of $t'$ and $t$. So, for $t \gg \hbar/\varepsilon$, the usual argument for Fermi’s golden rule yields the transition probability as

$$ P_{-j \to j}^{em} (t) = \sum_\mu |A_{fi}^\mu (t)|^2 \approx \Gamma_{-j \to j}^{em} t, \quad (4.34) $$

with

$$ \Gamma_{-j \to j}^{em} = \frac{2\pi}{\hbar} \sum_\mu \delta(\hbar \omega_\mu + \varepsilon) |\lambda_\mu|^2 \left| \sum_{a,b}' (\hat{k}_a^{\mu} e_b^\mu + \hat{k}_b^{\mu} e_a^\mu) T_{ab} \right|^2. \quad (4.35) $$

Once again, when we sum over phonon modes, we will end up integrating over all directions of $k$, and summing over polarizations. The details of how to perform these operations are also in Appendix A, and the final result can be cast into the standard form (2.15),

$$ \Gamma_{-j \to j}^{em} = \frac{\Lambda^2}{2\pi \rho \hbar^4} \frac{|\varepsilon|^3}{1 - e^{-\beta |\varepsilon|}} \left( G_{L}^{sc} + \frac{G_{T}^{sc}}{15 e_L^5} \right). \quad (4.36) $$

We have restored the Bose factor, and the superscript ‘sc’ stands for ‘semiclassical’. The quantities $G_{L}^{sc}$ and $G_{T}^{sc}$ are proportional to the ones with tildes in Eq. (A25) such that $G_{L}^{sc} = 15\tilde{G}_L/4\pi$ and $G_{T}^{sc} = 10\tilde{G}/4\pi$. For the special case of $C = H_x = 0$, it follows from
In contrast to what we found from perturbation theory, now $G_L \neq G_T$. If $D/E \gg 1$, however, the difference is small. We’ll see in Sec. V that the agreement between the two approaches is good, giving us confidence that both yield quantitatively reliable answers.

Equations (4.37) and (4.38) have the further virtue of being closed form answers. To be relevant to the actual experimental situation in Fe$_8$, however, we must allow $C \neq 0$. In this case, even if we use the modified value for $\Delta$, the factors of $D^2/E^2$ and $\Omega$ are likely to be incorrect, so we can expect the rate to be off by a factor of order unity. From the viewpoint of relevance to experiment, the most important case is when $H_x = 0$, and in that case we can evaluate $T_{ab}$ and then, $G_L$ and $G_T$, without excessive additional effort. We explain how to do this in Appendix B.

V. APPLICATION TO Fe$_8$

We now apply our calculations specifically to Fe$_8$, for which $j = 10$, $D = 0.292 \text{K}$, $E/D = 0.158$, and $C/D = -9.93 \times 10^{-5}$ [3]. For the spin-phonon interaction, we take $\Lambda = 0.25 \text{K}$ as an estimate for the coupling, and $\rho = 1.92 \text{g/cm}^3$ [39], which with the unit cell volume of 1496 Å$^3$ [39], and Debye temperature of 33 K reported in Ref. [40], implies an average sound speed of $\bar{c} = 1.4 \times 10^5 \text{cm/s}$, where the average is actually the cube root of the orientational and polarization average of the inverse cube of the phonon velocities as $k \to 0$. Within our model of an isotropic solid, assuming $c_L/c_T = 2$ (this is a typical ratio for common organic materials — 2.1 for polystyrene, 3.6 for polyethylene), these numbers yield,

$$\frac{\Lambda^2}{2\pi \rho \hbar^4} \times \frac{1}{15c_L^3} = 0.015 \text{s}^{-1}\text{K}^{-3}, \quad \frac{\Lambda^2}{2\pi \rho \hbar^4} \times \frac{1}{10c_T^3} = 0.72 \text{s}^{-1}\text{K}^{-3}. \quad (5.1)$$

(Since the speed of sound of the two modes occur to the third (for specific heat) or fifth (for the rate) power in the denominator, and since $c_L$ is usually larger than $c_T$, the transverse term will generally dominate for both the specific heat and the tunneling rate, and one could

$$G^\text{sc}_L = 8 \left(\frac{j^2 \Delta}{\hbar \Omega} \right)^2 \left(\frac{D^2}{E^2} + \frac{1}{2}\right), \quad (4.37)$$

$$G^\text{sc}_T = 8 \left(\frac{j^2 \Delta}{\hbar \Omega} \right)^2 \left(\frac{D^2}{E^2} - \frac{1}{3}\right). \quad (4.38)$$
In the following it will be useful to introduce the reduced magnetic field,

\[ h = \frac{g \mu_B H}{D_j}. \]  

(5.2)

First we compare the semiclassical result for \( \Gamma_{\text{em}}^{\text{j} \rightarrow j} \) with that obtained by perturbation theory. The physical prefactors and Bose occupation factors are the same in the two methods, so it remains to compare the dimensionless quantities \( G_L \) and \( G_T \), i.e. \( G_{L}^{\text{pt}} \) with \( G_{L}^{\text{sc}} \), and \( G_{T}^{\text{pt}} \) with \( G_{T}^{\text{sc}} \), noting that for the perturbative calculation \( G_{L}^{\text{pt}} = G_{L}^{\text{pt}} \). This is done in Table I for \( C = 0 \), and in Table II for \( C/D = -9.93 \times 10^{-5} \). We have put \( h_x = h_z = 0 \), and given answers for some other values of \( j \) beside 10, keeping \( E, D, \) and \( C \) the same. For the semiclassical data, we have taken \( \Delta \) from a direct numerical diagonalization of the pure spin Hamiltonian. We could in principle calculate \( \Delta \) also from the instanton method, but that is not the point of this paper.

We first note that \( G_{L}^{\text{sc}} \approx G_{T}^{\text{sc}} \), so it would not be too incorrect to speak of a single \( G^{\text{sc}} \) without distinguishing between its longitudinal and transverse values. Second, as can be seen, the agreement between the two approaches is quite good, with the differences being by about 10%. This is mainly because the perturbative method underestimates \( \Delta \), and if we had used this method to provide the input value of \( \Delta \) in Eq. (4.38) and its \( C \neq 0 \) analog, the differences would only be about 1.5%.

Next, let us consider how the rate varies with \( h_z \) (or \( \varepsilon \)). The dominant dependence is \( h_z^3 \) from the phase space plus Bose factor of \( |\varepsilon|^3/(1 - e^{-\beta|\varepsilon|}) \). There may, however, be an
Table II: Same as Table I, except with $C/D = -9.93 \times 10^{-5}$.

| $j$ | $G_{pt}$ | $G_{sc}^{L}$ | $G_{sc}^{T}$ |
|-----|----------|--------------|--------------|
| 5   | $1.485 \times 10^{-4}$ | $1.604 \times 10^{-4}$ | $1.558 \times 10^{-4}$ |
| 6   | $5.655 \times 10^{-6}$ | $6.272 \times 10^{-6}$ | $6.068 \times 10^{-6}$ |
| 7   | $2.375 \times 10^{-7}$ | $2.703 \times 10^{-7}$ | $2.606 \times 10^{-7}$ |
| 8   | $1.126 \times 10^{-8}$ | $1.317 \times 10^{-8}$ | $1.265 \times 10^{-8}$ |
| 9   | $6.085 \times 10^{-10}$ | $7.322 \times 10^{-10}$ | $7.001 \times 10^{-10}$ |
| 10  | $3.755 \times 10^{-11}$ | $4.655 \times 10^{-11}$ | $4.431 \times 10^{-11}$ |
| 11  | $2.641 \times 10^{-12}$ | $3.377 \times 10^{-12}$ | $3.200 \times 10^{-12}$ |
| 12  | $2.109 \times 10^{-13}$ | $2.788 \times 10^{-13}$ | $2.628 \times 10^{-13}$ |

additional dependence in the $G$’s. Finding this dependence with the instanton method is an unsolved problem (since the classical energy minima are no longer degenerate), but it is straightforward in the perturbative approach, where it arises from the $\varepsilon$ dependence of the energy denominators. We show this dependence in Fig. 1 for $j = 10$ with $C/D = -9.93 \times 10^{-5}$, and $h_x = 0$. We see that there is indeed a weak dependence on $\varepsilon$ at small fields. The change from the $h_z = 0$ value rises from less than 3% at $h_z = 0.02$ to 18% at $h_z = 0.06$. Note that we hit the next resonance (between $m = -10$ and $m = 9$) at $h_z \approx 0.1$.

We also show the semiclassical answers for $G_{sc}^{L}$ and $G_{sc}^{T}$ at $h_z = 0$; it can be seen that they serve as reasonable estimates for the entire range of $h_z$ values shown.

Lastly, we consider the general case when both $h_x$ and $h_z$ are non-zero. In Fig. 2 we look at plots of $G_{pt}$ vs $h_z$, for several values of $h_x$. (The curve for $h_x = 0$ is the same as in Fig. 1.) Note that with increasing $h_x$, the rate becomes smaller as a whole, and its $h_z$ dependence becomes more pronounced. The overall drop is because of interference. At $h_z = 0$, in particular, we will find that with increasing $h_x$, the $G$’s vanish, and so, consequently, does $\Gamma$. This is because we are approaching a diabolical point in $H$ space, where the pure spin problem tunnel splitting $\Delta$ vanishes. (For Fe$_8$, the first such point along $h_z = 0$ is at $h_x = 0.09345$, or $H_x = 0.203$T.)

VI. CONCLUSIONS

We have calculated the phonoemissive and phonoabsorptive tunnelling rates in single molecule magnets by two methods, perturbation theory, and instantons. The two methods
Figure 1: Plot of $G^{pt}$ as a function of external applied field $h_z$ along the easy axis (solid blue line), for $j = 10$ with $C/D = -9.93 \times 10^{-5}$, and $h_x = 0$. Note that the resonance between $m = -j$ and $m = j - 1$ when $j = 10$ is located at $h_z = 0.1$. We also show the $h_z = 0$ values of $G_{L}^{sc}$ (dotted red line) and $G_{T}^{sc}$ (dashed red line), with all other parameters the same.

Figure 2: Plot of $G^{pt}$ as a function of external applied field $h_z$, for various values of $h_x$, and all other parameters at the values for Fe$_8$. Note that the intersections exhibited around $h_z = 0.06$ do not all occur at the same location.
agree quite well. How do our calculations compare with previous work [20, 21]? Reference [20] is concerned entirely with the case where $D = 0$, but it is still possible to consider its general approach. This paper employs not the spin states $|j, m\rangle$, which are the eigenstates of $J_z$, but rather the states $|j, m^*\rangle$, which are linear combinations of the exact eigenstates of the pure spin Hamiltonian such that the wavefunction is localized in one well or the other. In most cases of interest one works with the state $|j, \pm j^*\rangle$, which are formed from the two lowest lying eigenstates. These states were determined approximately by considering just the exponential fall-off into the opposite well, ignoring their modification due to the actual shape of the potential. Nevertheless, if we were to apply this method to the present problem with $D \neq 0$, we believe we would find comparable answers. One limitation of this technique is that it is difficult to do analytic calculation when there are several types of anisotropy (terms $D$, $C$, and $H_x$ terms).

Alternatively, the meaning of the matrix elements between states $|j, \pm j^*\rangle$ finds a natural interpretation through the semiclassical calculation, via the method of instantons. Since the instantons are the classical trajectories for the full spin Hamiltonian $\mathcal{H}^s$ and not just its diagonal part $\mathcal{H}_0 - \mathcal{H}^p$, the first order perturbation in $\mathcal{H}^{pp}$ via these instantons captures the intentions of $|j, \pm j^*\rangle$.

In Ref. [21] on the other hand, $\Gamma$ was obtained by doing a second order Fermi golden rule calculation taking only the $m = \pm 9$ states as intermediates, and using experimental data [3] to obtain the amplitudes $\Delta_{-10,9}$ and $\Delta_{9,-10}$. This is like the perturbative calculation of the present paper, except that $\mathcal{H}^{pp}$ is restricted to act at either the first or last step of the available paths. We do not have a strong justification for this approximation, and that is partly what drove this paper. Nevertheless, we find that our answers are consistent with this calculation also.

Lastly let us consider the absolute value of the tunneling rate. Here we return to $H_x = 0$. The most significant term in (3.24) is $G^\text{pt}_T$, which is a very small number that is also independent of the unknowns $\Lambda$, $c_L$, $c_T$, and $\rho$. Over the relevant values of $H_z$, $G^\text{pt}_T$ is of order $10^{-11}$. If we take $h_z$ to be such that the local bias is $\varepsilon \sim 0.1 \text{K}$, then at zero temperature the tunneling rate is $2.7 \times 10^{-14} \text{s}^{-1}$. As argued in Ref. [21], even with uncertainties in the magnetoelastic coupling and sound speeds, its order of magnitude is too small to explain the experimental magnetization data, and so the problem of how single molecule magnets get magnetized starting from a demagnetized state remains open. It also remains an open
question if the rates calculated in this paper could be measured directly.

Appendix A: Summing over Phonon Polarizations and Directions

The purpose of this Appendix is to show how to sum over phonon polarizations and directions. For the perturbation theory calculation, we must carry out this sum for $|\mathcal{F}^{ks}|^2$, where $\mathcal{F}^{ks}$ is given by Eq. (3.19), which we reproduce here for ready reference:

$$\mathcal{F}^{ks} = -i\lambda_{ks} [\hat{k}_- e_s^a M_2 + (\hat{k}_- e_z^s + \hat{k}_z e_s^a) M_1].$$

(A1)

The fundamental fact that permits us to simplify the expression for the rate is that for any $\mathbf{k}$, the polarization vectors are a complete set. Hence,

$$\sum_s e_s^a e_s^b = \delta_{ab}.$$  \hspace{1cm} (A2)

Further, it is clear that for the longitudinal mode ($s = L$), $e^{ks} = \hat{k}$. Hence,

$$e^L_a e^L_b = \hat{k}_a \hat{k}_b,$$  \hspace{1cm} (A3)

It follows that

$$\sum_{s \neq L} e_s^a e_s^b = \delta_{ab} - \hat{k}_a \hat{k}_b.$$  \hspace{1cm} (A4)

Secondly,

$$\int d^2\hat{k} \hat{k}_z^2 = \frac{4\pi}{3}, \quad \int d^2\hat{k} \hat{k}_z^4 = \frac{4\pi}{5}.$$  \hspace{1cm} (A5)

Eqs. (A3), (A4), and (A5) are our basic working tools.
We have

\[
\frac{|\mathcal{F}_{ks}|^2}{|\lambda_{ks}|^2} = |\hat{k}_- e_s^s|^2 |M_2|^2 + |\hat{k}_- e_s^s + \hat{k}_z e_s^s|^2 |M_1|^2 + (\hat{k}_- e_s^s)(\hat{k}_+ e_s^s + \hat{k}_z e_s^s)M_2M_1 + \text{c.c.},
\]

(A6)

where the overbar denotes the complex conjugate. We consider the coefficients of $|M_2|^2$, $|M_1|^2$, and $M_2 \bar{M}_1$ separately.

**Coefficients of $|M_2|^2$:** We have

\[
|\hat{k}_- e_s^s|^2 = (\hat{k}_x^2 + \hat{k}_y^2)(e_x^s e_x^s + e_y^s e_y^s).
\]

(A7)

Hence,

\[
|\hat{k}_- e_s^L|^2 = 1 - 2\hat{k}_z^2 + \hat{k}_z^4,
\]

(A8)

\[
\sum_{s \neq L} |\hat{k}_- e_s^s|^2 = 1 - \hat{k}_z^4,
\]

(A9)

and

\[
\int d^2k |\hat{k}_- e_s^L|^2 = \frac{32\pi}{15},
\]

(A10)

\[
\int d^2k \sum_{s \neq L} |\hat{k}_- e_s^s|^2 = \frac{48\pi}{15}.
\]

(A11)

**Coefficients of $|M_1|^2$:** Now,

\[
|\hat{k}_- e_s^s + \hat{k}_z e_s^s|^2 = (\hat{k}_x^2 + \hat{k}_y^2)(e_x^s e_x^s + e_y^s e_y^s) + \hat{k}_- \hat{k}_z e_x^s e_x^s + \hat{k}_+ \hat{k}_z e_y^s e_y^s.
\]

(A12)

A short and straightforward calculation shows that,

\[
|\hat{k}_- e_s^L + \hat{k}_z e_s^L|^2 = \hat{k}_z^2 - \hat{k}_z^4,
\]

(A13)

\[
\sum_{s \neq L} |\hat{k}_- e_s^s + \hat{k}_z e_s^s|^2 = 1 - 3\hat{k}_z^2 + 4\hat{k}_z^4.
\]

(A14)
Hence,

\[ \int d^2\hat{k} |\hat{k}_- e^L_+ + \hat{k}_+ e^L_-|^2 = \frac{32\pi}{15}, \quad (A15) \]

\[ \int d^2\hat{k} \sum_{s \neq L} |\hat{k}_- e^s_+ + \hat{k}_+ e^s_-|^2 = \frac{48\pi}{15}. \quad (A16) \]

**Coefficients of** $M_2\bar{M}_1$: This time, we need

\[ (\hat{k}_- e^s_-)(\hat{k}_+ e^s_+ + \hat{k}_+ e^s_-) = (k^2_x + \hat{k}_y^2)e^s_- e^s_+ + \hat{k}_- \hat{k}_2 e^s_+(e^s_x e^s_x + e^s_y e^s_y). \quad (A17) \]

Therefore,

\[ (\hat{k}_- e^L_+)(\hat{k}_+ e^L_+ + \hat{k}_+ e^L_-) = \hat{k}_z \hat{k}_- (1 - \hat{k}_2^2), \quad (A18) \]

\[ \sum_{s \neq L}(\hat{k}_- e^s_-)(\hat{k}_+ e^s_+ + \hat{k}_+ e^s_-) = \hat{k}_2^2 \hat{k}_-, \quad (A19) \]

but both these terms vanish upon integrating over $\hat{k}$. Hence there is no term involving $M_2\bar{M}_1$, or its complex conjugate, $\bar{M}_2M_1$.

Equations (A10), (A11), (A15), and (A16) lead immediately to Eq. (3.23).

The sums over $s$ and $\hat{k}$ required in Sec. IV are of a slightly different form, and best performed as follows.

For phonon polarization $s$, we define,

\[ g_s = \sum_{a,b} (\hat{k}_a e^s_b + \hat{k}_b e^s_a)T_{ab}, \quad (A20) \]

and

\[ \tilde{G}_L \equiv \int d^2\hat{k} g_L \bar{g}_L, \quad \tilde{G}_T \equiv \int d^2\hat{k} \sum_{s \neq L} g_s \bar{g}_s. \quad (A21) \]

We may regard $T_{ab}$ as a general tensor at this point, not necessarily equal to the one defined in Sec. IV. This tensor may clearly be taken as symmetric, since any antisymmetric part drops out in the result for $g_s$. It pays to defer setting $T_{zz}$ to zero.
It is now easy to show that

\[
\tilde{G}_L = \frac{16\pi}{15} T_{ab} \bar{T}_{cd} (\delta_{ab}\delta_{cd} + \delta_{ac}\delta_{bd} + \delta_{ad}\delta_{bc}) \\
= \frac{16\pi}{15} (T_{aa} \bar{T}_{bb} + 2T_{ab} \bar{T}_{ab}),
\]

where there is an implicit sum over repeated indices. To find \(\tilde{G}_T\), we use the completeness of the \(e_a^s\)’s to first show that

\[
\tilde{G}_L + \tilde{G}_T = \frac{16\pi}{3} T_{ab} \bar{T}_{ab}.
\]

Hence,

\[
\tilde{G}_T = \frac{16\pi}{15} (3T_{ab} \bar{T}_{ab} - T_{aa} \bar{T}_{bb}).
\]

Writing out the implicit sums explicitly, and setting \(T_{zz}\) to zero, we have

\[
\tilde{G}_L = \frac{16\pi}{15} \left(3|T_{xx}|^2 + 3|T_{yy}|^2 + T_{xx} \bar{T}_{yy} + T_{yy} \bar{T}_{xx} + 4|T_{xy}|^2 + 4|T_{xz}|^2 + 4|T_{yz}|^2\right),
\]

\[
\tilde{G}_T = \frac{16\pi}{15} \left(2|T_{xx}|^2 + 2|T_{yy}|^2 - T_{xx} \bar{T}_{yy} - T_{yy} \bar{T}_{xx} + 6|T_{xy}|^2 + 6|T_{xz}|^2 + 6|T_{yz}|^2\right).
\]

**Appendix B: Evaluation of \(T_{ab}\) for \(H_x = 0\)**

In this Appendix, we discuss how to evaluate the expression (4.31) for \(T_{ab}\) for the Fe\(_8\) problem, especially for \(C \neq 0\). The instantons with \(C \neq 0\) were considered in Ref. [36], but the focus there was on the non-interfering ones with \(H_x \neq 0\). Here, we are more interested in the time dependence of the interfering instantons when \(H_x = 0\).

In the absence of any external field, the Fe\(_8\) Hamiltonian is

\[
\mathcal{H} = -D J_z^2 + E(J_x^2 - J_y^2) + C(J_+^4 + J_-^4).
\]

The equations of motion for the instanton entail \(h(z, \bar{z}) \equiv \langle z | \mathcal{H} | \bar{z} \rangle\). Keeping only the leading order in \(j\) for the coherent state expectation value of each term, we obtain

\[
h(z, \bar{z}) = 2j^2 D \left[ -\frac{1}{2}s_z^2(z, \bar{z}) + \frac{\alpha}{2}(s_x^2(z, \bar{z}) - s_y^2(z, \bar{z})) + \gamma \frac{z^4 + \bar{z}^4}{(1 + z\bar{z})^4} + \frac{1}{2} \right].
\]

The additive constant in \(h\) has been adjusted to make the minimum energy equal to zero,
and we have introduced
\[ \alpha = \frac{E}{D}, \quad \gamma = 8j^2\frac{C}{D}. \] (B3)

Instead of \( z, \bar{z}, \) or \( s_a, \) it is best to work in Archimedean cylindrical coordinates \( s_z \) and \( \phi, \)
given by
\[ z = \sqrt{1 + s_z e^{i\phi}}, \quad \bar{z} = \sqrt{1 + s_z e^{-i\phi}}, \] (B4)
\[ s_x = \sqrt{1 - s_z^2} \cos \phi, \quad s_y = \sqrt{1 - s_z^2} \sin \phi. \] (B5)

In these coordinates,
\[ h(s_z, \phi) = 2j^2 D(1 - s_z^2) \left[ \frac{1}{2} + \frac{\alpha}{2} \cos(2\phi) + \frac{\gamma}{8}(1 - s_z^2) \cos(4\phi) \right], \] (B6)
and the equations of motion read
\[ \frac{ds_z}{dt} = -\frac{1}{j} \frac{\partial h}{\partial \phi}, \quad \frac{d\phi}{dt} = \frac{1}{j} \frac{\partial h}{\partial s_z}. \] (B7)

We now continue to imaginary time via \( t \rightarrow -i\tau, \) and also define \( \tilde{\phi} = i\phi. \) Then
\[ s_x = \sqrt{1 - s_z^2} \cosh \tilde{\phi}, \quad s_y = -i \sqrt{1 - s_z^2} \sinh \tilde{\phi}, \] (B8)
the Hamiltonian reads
\[ h(s_z, \tilde{\phi}) = 2j^2 D(1 - s_z^2) \left[ \frac{1}{2} + \frac{\alpha}{2} \cosh(2\tilde{\phi}) + \frac{\gamma}{8}(1 - s_z^2) \cosh(4\tilde{\phi}) \right], \] (B9)
and the equations of motion become
\[ \frac{ds_z}{d\tau} = -\frac{1}{j} \frac{\partial h}{\partial \tilde{\phi}}, \quad \frac{d\tilde{\phi}}{d\tau} = \frac{1}{j} \frac{\partial h}{\partial s_z}. \] (B10)

The usual program now is to exploit the conservation of energy to find the instantons. Setting \( h(s_z, \tilde{\phi}) = 0 \) will give us the solution(s) for \( \cosh \tilde{\phi}(s_z), \) which can be fed into the equation for \( ds_z/d\tau \) and used to solve for \( s_z(\tau). \) It pays to consider the \( C = 0 \) case separately first, as that helps avoid pitfalls in the \( C \neq 0 \) case.

**Case I.** \( C = 0: \) Setting \( h = 0 \) with \( C = 0 \ (\gamma = 0) \) in Eq. (B9) yields the non-tunneling
solutions \( s_z = \pm 1 \), as well as the tunneling one:

\[
\cosh(2\bar{\phi}) = -\frac{1}{\alpha^2}.
\]  

(B11)

Along this solution, \( \alpha \sinh(2\bar{\phi}) = \pm \sqrt{1 - \alpha^2} \), and the equation of motion becomes

\[
\frac{ds_z}{d\tau} = \pm 2jD\sqrt{1 - \alpha^2}(s_z^2 - 1),
\]  

(B12)

which, with \( \hbar\Omega \equiv 2jD\sqrt{1 - \alpha^2} \), gives

\[
s_z = \pm \tanh \Omega(\tau - \tau_c).
\]  

(B13)

The two signs here describe tunneling in opposite directions, from \(-\hat{z}\) to \(\hat{z}\), and from \(\hat{z}\) to \(-\hat{z}\), not the two interfering instantons. Let us pick the one with the plus sign, wherein \( s_z \) goes from \(-1\) to \(1\). For this solution, we may obtain the other two Cartesian components of \( s \) by noting that

\[
\cosh^2 \bar{\phi} = \frac{1}{2} (\cosh(2\bar{\phi}) + 1), \quad \sinh^2 \bar{\phi} = \frac{1}{2} (\cosh(2\bar{\phi}) - 1).
\]  

(B14)

The oppositely winding, interfering solutions arise from the two different branches of the square root, which introduces a relative phase of \( \pi \) between them. In particular, for \( \alpha < 1 \), both \( \cosh(2\bar{\phi}) \pm 1 \) will be negative. (Note that since we have chosen \( \sinh(2\bar{\phi}) = +\sqrt{1 - \alpha^2}/\alpha \), once a sign for \( \cosh\bar{\phi} \) is picked, that for \( \sinh\bar{\phi} \) is also fixed.)

**Case II.** \( C \neq 0 \): Setting \( h = 0 \) with \( C \neq 0 \) leads to the tunneling solutions

\[
\cosh(2\bar{\phi}) = \frac{\alpha \pm \sqrt{\alpha^2 - \frac{1}{2}\gamma(1-s_z^2)(4-\gamma(1-s_z^2))}}{\gamma(1-s_z^2)}.
\]  

(B15)

Of these two solutions, we must choose the one with the relative “−”, since in that case (see Fig. 3),

\[
\lim_{s_z \to \pm 1} \cosh(2\bar{\phi}) = -\frac{1}{\alpha},
\]  

(B16)

and since this is a finite quantity, \( s_x \) and \( s_y \) will vanish as \( s_z \to \pm 1 \). We are thus assured that this solution will approach \( s = \pm \hat{z} \) at the end points, which, as shown in Ref. \[36\] is the
Figure 3: Plot of $\cosh(2\bar{\phi})$ as a function of $s_z$, for the case with $C/D = 0$ (dashed lines) and $C/D = -9.93 \times 10^{-5}$ (solid lines)

hallmark of the *interfering instantons*. The other solutions do not approach $\pm \hat{z}$, i.e., do not start and end on the real two-sphere, and are thus the noninterfering or jump instantons.

Another way to think about this is to take the limit $\gamma \to 0$ since the term $(1 - s_z^2)$ is always paired up with $\gamma$. Again, the solution with a relative “−” is the continuation of the $\gamma = 0$ case, whereas the “+” solution diverges as $\gamma \to 0$, and is new. This equation reveals the singular nature of the fourth order perturbation.

From now on, we consider the interfering instantons only since these are the ones for which the real part of action is the least. Feeding that solution for $\cosh(2\bar{\phi})$ into the equation of motion, we obtain a differential equation of the form

$$\frac{ds_z}{d\tau} = f(s_z),$$

where the functional form of $f$ is very cumbersome, but (for the parameters relevant to Fe$_8$ at the least) has the following properties (see Fig. 4):

1. $f(-s_z) = f(s_z)$.
2. $f(\pm 1) = 0$. 
Figure 4: Plot of \( f(s_z) \) in (B17) as a function of \( s_z \), for the case with \( C/D = 0 \) (dashed line) and \( C/D = -9.93 \times 10^{-5} \) (solid line), with \( H_x = 0 \) in both cases. The other parameters are as for Fe8.

3. \( f(s_z) \) is real for \( s_z \in [-1,1] \).

This shows that we can find a real solution for \( s_z(\tau) \) that connects the endpoints \( \pm 1 \). Therefore, instead of solving Eq. (B17), we can use \( ds_z/f(s_z) \) as a change of measure for \( d\tau \). We use this to evaluate the integral in Eq. (4.31). We first use the fact that the instanton depends only on \( \tau - \tau_c \) to write

\[
\int_{-\infty}^{\infty} d\tau_c s_a(q, \tau_c; \tau)s_b(q, \tau_c; \tau) = \int_{-\infty}^{\infty} d\tau s_a(q, \tau_c; \tau)s_b(q, \tau_c; \tau). \tag{B18}
\]

We then transform the integral to one over \( s_z \), from \(-1\) to \(+1\), along the real axis,

\[
\int_{-1}^{1} \frac{ds_z}{f(s_z)} s_a(q, \tau_c; \tau)s_b(q, \tau_c; \tau). \tag{B19}
\]

Since \( s_x \) and \( s_y \) can be obtained as functions of \( s_z \), the numerical evaluation of this integral is straightforward.

One immediate consequence of this procedure is that since \( s_x \), \( s_y \), and \( f(s_z) \) are all even functions of \( s_z \), while \( s_z \) is trivially odd, \( T_{xz} \) and \( T_{yz} \) vanish by oddness of the integrand.
This agrees with our perturbative result that for integer $j$ the $\Delta m = 1$ terms vanish when $H_x = 0$, and with the explicit instanton calculation for $C = 0$. Furthermore, the remaining integrals in $T_{xx}$, $T_{xy}$, and $T_{yy}$ are insensitive to the sign of $q$ (the winding), since either $s_x$ and $s_y$ both have a positive sign, or both have a negative sign. Hence the sum over $q$ will once again produce the tunnel splitting $\Delta$ precisely.

We conclude the Appendix by noting that our symmetry arguments fail when $H_x \neq 0$. The function $f(s_z)$ is no longer purely real for $s_z \in [-1,1]$, so we cannot claim that the trajectory $s_z(\tau)$ lies entirely along the real axis from $-1$ to $1$. The $\Delta m = 1$ terms no longer vanish, and the sum over windings produces $W \cos(1/2 \Theta + \zeta)$, where $\zeta$ is a nonzero additional phase, so while the $T_{ab}$’s are still of order $\Delta$, they are not all strictly proportional to it.

[31] This is the simplest form consistent with the general symmetry properties of the magnetoelastic tensor, \(\Lambda_{abcd} = \Lambda_{bacd} = \Lambda_{abdc}\). One might wonder if a term like \(\Lambda'\delta_{ab}\delta_{cd}\) should also be included. The answer is no, because it would be proportional to \(\mathcal{J} \cdot \mathcal{J}\) which is a constant. Thus, such
a term would involve only the phonons, and because it was linear in the strain, would imply
the existence of a nonzero strain in equilibrium. Since we wish to regard the equilibrium state
as unstrained, i.e., measure strain with reference to this state, we set $\Lambda' = 0$.

Park, CA 1969), pp. 257–258.

[33] Since the different terms can have different signs (or complex-valued phases in general), the
addition of contributions from different paths can give rise to interference. In the perturbative
point of view, it is this interference that underlies the diabolical points in the tunneling spec-
trum, and as found in Ref. [26] keeping the lowest order terms of each qualitatively different
class of discrete paths gives a quantitatively good account of the locations of the diabolical
points.
