Nowadays, magnetoresponsive soft materials, based not simply on magnetic nanoparticles, but rather on multiple components with distinct sizes and magnetic properties, both in liquid and polymeric carriers, are becoming more and more wide-spread due to their unique and versatile macroscopic response to an applied magnetic field. The variability of the latter is related to a complex interplay of the magnetic interactions in a highly non-uniform internal fields caused by spatial inhomogeneity in multicomponent systems. In this work, we present a combine analytical and simulation study of binary superparamagnetic systems, containing nanoclusters and dispersed single-domain nanoparticles, both in liquid and solid carrier matrices. We investigate the equilibrium magnetic response of these systems in wide ranges of concentrations and interaction energies. It turns out that, while the magnetisation of a binary solid can be both above and below that of an ideal superparamagnetic gas, depending on the concentration of the dispersed phase and the interparticle interactions, the system in a liquid carrier is highly magnetically responsive. In liquid, a spatial redistribution of the initially homogeneously dispersed phase in the vicinity of the nanocluster is observed – the effect that is reminiscent of the so-called “haloing” effect previously observed experimentally on micro- and milli-scales.

I. INTRODUCTION

Magnetic soft matter is a family of artificially synthesized materials based on a distributed system of magnetic particles embedded in a non-magnetic carrier matrix. Notable members of the said family are ferrofluids [1], magnetorheological fluids [2], ferrogels [3] and magnetoactive elastomers [4]. The behavior and properties of these systems can be controlled using applied magnetic fields, which makes them highly attractive in various branches of nanotechnology and nanomedicine. Examples of applications include soft crawling robots [5], tissue engineering scaffolds [6], adaptive dampers and seals [7], ferrofluid cooling systems [8], magnetic lubricants [9], targeted drug delivery systems [10], magnetic hyperthermia of cancer [11] and magnetic particle imaging [12].

Modern methods of magnetic soft matter synthesis have achieved a tremendous success. In particular, particles can vary greatly in size and can have very different internal magnetic structure. The common types of particles are single-domain ferro- or ferrimagnetic nanoparticles with linear sizes \(\sim 10\ \text{nm} [13]\), dense cluster of single-domain nanocrystals (magnetic “nanoflowers” [14] and “multicore nanoparticles” [15, 16] with the size of the order of \(\sim 10^2\ \text{nm}\)) and multi-domain microparticles with low or high coercivity [17]. Recently, multicomponent systems, which simultaneously employ several types of magnetic particles, attracted a lot of scientific attention. For instance, these are hybrid elastomers containing both magnetically soft and hard microparticles [18]. Reportedly, they allow for a much larger degree of a magnetomechanical fine-tuning than analogous one-component systems [19]. In Ref. [20], an elastic sphere filled with magnetically saturated colloidal particles of two different sizes was considered – it was shown that for certain spatial arrangements of particles, variation in the quantitative ratio between small and large particles can lead to qualitative changes in the system overall deformation response. Another example are bimodal magnetorheological fluids, which consist of magnetic microparticles submerged in a nanodispersed ferrofluid [21]. They are considered to be an improved substitution for conventional magnetorheological fluids due to their superior colloid stability and sedimentation behavior [22, 23]. Recently, a novel type of binary ferrofluids containing a mixture of magnetically hard and magnetically soft nanoclusters was experimentally investigated in Ref. [24]. Even some samples of traditional ferrofluids are known to contain a fraction of large nanoclusters, which results in a substantial alteration of their magnetic, mass-transport and rheological properties [25–28].

The more the magnetic soft matter systems that contain two types of magnetic components are developed, the clearer becomes the demand to understand the fundamental interplay between interactions of those compo-

* andrey.kuznetsov@univie.ac.at
ments and their impact on the system overall magnetic response. The latter is of particular importance as it forms the basis for the efficient usage of these materials.

Here, we will focus mainly on composite materials that are based on single-domain fine particles. It is known that if the internal anisotropy energy of such particles is comparable or smaller than the energy of thermal fluctuations (which is common for iron oxide nanoparticles [13]), then the average ensemble magnetization in zero field is zero. As the field increases, the magnetization will non-linearly and reversibly grow towards the saturation value. Such behaviour is known as "superparamagnetism" and corresponding materials can be referred to as "superparamagnetic" [29]. While interactions in one-component superparamagnetic systems are very important, both in liquid [30, 31] and solid [32, 33] carriers, the situation becomes even more complex, if the material is multi-component. A clear evidence of this are direct and inverse ferrofluid emulsions that are binary systems with only one magnetic component [34–37]. Here, the non-uniformity of the internal magnetic field inside the sample leads to a very sophisticated magnetic response. It is, however, clear that the internal field gradients will become even stronger and more important, if a true binary magnetic material is addressed. So far, a detailed description as well as a fundamental understanding of the magnetisation processes in such materials is not available in the scientific literature. This work aims at filling this gap and puts forward a combined analytical-computational study of a system, containing both large superparamagnetic nanoclusters (the sources of strong internal field and spatial inhomogeneity) and a dispersed phase of single-domain superparamagnetic particles that are forced to react to the perturbations created by the cluster. As long as we expect a drastic change depending on the carrier, we investigate two extreme cases: the disperse phase is either frozen in space, maintaining only rotational degrees of freedom, mimicking a material, based on a rubber-like rigid matrix; or the whole system is immersed in a liquid, where the disperse phase can freely diffuse. It turns out that in the latter, a pronounced gathering of a dispersed phase in the vicinity of the nanocluster is observed, causing qualitative changes in the magnetisation behaviour.

The article is organised as follows. First, we describe the model in detail in Sec. II. In Sec. III, we adapt the analytical approach, developed by Subbotin [35, 36], and calculate the magnetization of our binary system. The results and discussions in Sec. IV are split, according to the carrier: we discuss solid matrix in IV A; a liquid carrier is studied in IV B and IV C of the Results. In particular, spatial redistribution of a dispersed phase is investigated in Sec. IV C. The summary and a short outlook are provided in Sec. V.

II. MODEL OF A BINARY SUPERPARAMAGNETIC MIXTURE

The system under consideration is an isolated magnetic nanocluster embedded in a superparamagnetic medium (see Fig. 1). The system is subjected to an external uniform magnetic field \( \vec{H}_0 \) and thermostated at a constant temperature \( T \). Nanocluster is modelled as a sphere of diameter \( D_{cl} \) filled with \( N_{in} \) spherical magnetic particles of diameter \( d \). Particles are distributed within the cluster randomly and uniformly, without overlapping, their volume fraction is

\[
\varphi_{in} = \frac{v}{V_{cl}} = N_{in} \left( \frac{d}{D_{cl}} \right)^3 ,
\]

where \( v = (\pi/6)d^3 \) and \( V_{cl} = (\pi/6)D_{cl}^3 \) are volumes of the particle and the nanocluster, respectively. Positions of particles within the nanocluster are rigidly fixed. Particles are assumed to be single-domain and magnetically-isotropic (the validity of this approximation is commented on in Appendix A). Each particle has a magnetic moment \( \vec{m} \), which magnitude is fixed, but its orientation can change under the influence of an applied magnetic field, dipolar magnetic fields created by other magnetic moments in the system and thermal fluctuations. As a result, the nanocluster as a whole will exhibit a superparamagnetic behaviour according to the definition introduced in the previous section. It does not have a net magnetic moment in the absence of an applied field, but will be non-linearly magnetized, if the field is turned on [38]. The superparamagnetic medium surrounding the nanocluster is modelled in a similar fashion. It consists of \( N_{ex} \) magnetically-isotropic spherical single-domain particles, which are exactly the same as particles that constitute the cluster, i.e. they also have diameter \( d \) and rotatable magnetic moment \( \vec{m} \). The particle volume fraction in the medium is

\[
\varphi_{ex} = N_{ex} \frac{v}{V_{tot} - V_{cl}} ,
\]
where $V_{tot}$ is the total system volume. Magnetic nanoparticles in the medium always retain their rotational degrees of freedom.

The interaction of magnetic moments with the external field is governed by the Zeeman potential

$$U_Z = -\mu_0 (\vec{m} \cdot \vec{H}_0),$$  \hspace{1cm} (3)

where $\mu_0$ is the magnetic permeability of vacuum. Additionally, each pair of particles interacts via the magnetic dipole-dipole potential

$$U_{dd}(i, j) = \frac{\mu_0}{4\pi} \frac{m_i}{r_{ij}^3} - \frac{3}{r_{ij}^5} (\vec{m}_i \cdot \vec{r}_{ij}) (\vec{m}_j \cdot \vec{r}_{ij}),$$  \hspace{1cm} (4)

where $\vec{m}_i$ and $\vec{m}_j$ are magnetic moments of two particles and $\vec{r}_{ij}$ is the vector connecting their centers. We use two dimensionless energy parameters to characterize these magnetic interactions. The first one is the Langevin parameter

$$\xi_0 = \frac{\mu_0 m H_0}{k_B T},$$  \hspace{1cm} (5)

that is the ratio of the Zeeman energy to the thermal energy $k_B T$, $k_B$ is the Boltzmann constant, $m = |\vec{m}_i|$. For a ten nanometer magnetite grain (with the saturation magnetization $M_s = 450$ kA/m), $\xi_0 = 1$ corresponds to $H \simeq 14$ kA/m at room temperature. The second parameter is the so-called dipolar coupling constant

$$\lambda = \frac{\mu_0 m^2}{4\pi d^3 k_B T},$$  \hspace{1cm} (6)

that is the characteristic energy scale of two adjacent particles, whose dipoles are aligned head-to-tail, divided by $k_B T$ and calculated per particle. At $T = 300$ K, this parameter for a pair of magnetite grains will roughly go from $\lambda \sim 1$ to $\lambda \sim 10$ as their diameter increases from 10 to 20 nanometers.

Modelling of different carriers will be done by changing the way we treat the translational degrees of freedom of our particles. In a solid carrier matrix (SCM), single-domain particles surrounding the cluster will be randomly distributed in the medium and would not be able to move (just like the particles that constitute the nanochuster itself). In a liquid carrier matrix (LCM), particles will be subjected to a translational Brownian motion and could change their position relative to the nanochuster. They are assumed to be sterically stabilized and are not allowed to overlap. Of course, in a liquid the nanochuster should undergo the Brownian motion as well. However, we can make use of the fact that characteristic time scales for 3D Brownian motion of a cluster and a particle, $\tau_{cl} = 3\eta V_{cl}/k_B T$ and $\tau_p = 3\eta\nu/k_B T$, respectively ( $\eta$ is the carrier viscosity), are very different. Indeed, if $D_{cl}/d \sim 10$, the cluster motion is three orders of magnitude slower than that of surrounding particles. Thus, in LCM simulations the cluster will be treated as if its position is fixed.

Our main quantities of interest in this work are the normalized equilibrium magnetic moment of the nanochuster

$$\vec{M}_{cl} = \left( \sum_{i=1}^{N_{in}} \vec{m}_i \right) \frac{1}{m N_{in}},$$  \hspace{1cm} (7)

as well as the total normalized magnetic moment of the whole system

$$\vec{M}_{tot} = \left( \sum_{i=1}^{N_{tot}} \vec{m}_i \right) \frac{1}{m N_{tot}},$$  \hspace{1cm} (8)

where $N_{tot} = N_{in} + N_{ex}$ is the total number of particles in the system, $\langle \ldots \rangle$ denotes an ensemble average.

In this work, we use both analytical theory (Section III) and Langevin dynamics simulations (for details, see Appendix B). However, already at this point, it is important to specify that the system in simulations is subjected to 3D periodic boundary conditions. It approximately corresponds to a suspension of nanochusters with a nanochuster volume fraction

$$\Phi_{cl} = \frac{V_{cl}}{V_{tot}} = \left( 1 + \frac{\varphi_{in} N_{ex}}{\varphi_{ex} N_{in}} \right)^{-1}.$$  \hspace{1cm} (9)

We will consider systems with $N_{in} = 500$ and $N_{ex} = 2500$. Particle concentration in the cluster is always $\varphi_{in} = 0.3$ (correspondingly, $D_{cl} \simeq 12 d$), while the concentration of the surrounding medium will be changed from a small value of $\varphi_{ex} = 0.002$ to $\varphi_{ex} = 0.15$. Correspondingly, the cluster concentration will change from $\Phi_{cl} \simeq 0.0013$ to $\Phi_{cl} \simeq 0.09$. Magnetic interaction parameters also will vary in wide ranges: $1 \leq \lambda \leq 5$, $0 \leq \xi_0 \leq 5$.

### III. MAGNETIC RESPONSE THEORY

In this section, we will summarize the works of Subbotin on inverse ferroemulsions [35, 36] and adapt them to binary superparamagnetic mixtures. Let us consider a suspension of spherical magnetizable bodies (clusters) in a magnetizable medium with a relative magnetic permeability $\mu_{ex}$. Assume that the volume fraction of clusters is $\Phi_{cl}$ and they are made of some material with relative magnetic permeability $\mu_{in}$. According to Refs. [35, 36], the field inside clusters is homogeneous and parallel to the external field, its magnitude is given by

$$H_{in} = H_0 \frac{1}{1 + (1 - \Phi_{cl}) k (\frac{\mu_{in}}{\mu_{ex}} - 1)},$$  \hspace{1cm} (10)

where $k$ is the cluster demagnetization factor. For a sphere, $k = 1/3$. The field in the surrounding medium is

$$H_{ex} = H_0 \left[ 1 + \frac{\Phi_{cl} k (\frac{\mu_{in}}{\mu_{ex}} - 1)}{1 + (1 - \Phi_{cl}) k (\frac{\mu_{in}}{\mu_{ex}} - 1)} \right].$$  \hspace{1cm} (11)
Permeabilities, in general, can be considered as non-linear functions of the field:

\[
\mu_{\text{in}} = 1 + \frac{M_{\text{in}}(H_{\text{in}})}{H_{\text{in}}},
\]
\[
\mu_{\text{ex}} = 1 + \frac{M_{\text{ex}}(H_{\text{ex}})}{H_{\text{ex}}},
\]

where \( M_{\text{in}} \) and \( M_{\text{ex}} \) are magnetizations of the cluster material and of the medium, respectively. The total magnetization of the system is

\[
M_{\text{tot}} = \Phi_{\text{el}}M_{\text{in}}(H_{\text{in}}) + (1 - \Phi_{\text{el}})M_{\text{ex}}(H_{\text{ex}}).
\]

Normalized magnetic moments then can be found as

\[
M_{\text{el}} = \frac{M_{\text{in}}V_{\text{el}}}{m_{\text{N}}}, \quad 0 \leq M_{\text{el}} \leq 1,
\]
\[
M_{\text{tot}} = \frac{M_{\text{tot}}V_{\text{tot}}}{m_{\text{Ntot}}}, \quad 0 \leq M_{\text{tot}} \leq 1.
\]

Further on, the set of equations (10)–(16) will be referred to as the binary mixture magnetization (BMM) model.

The key assumption of BMM is that magnetic field in the medium \( H_{\text{ex}} \) is a sum of the external field \( H_0 \) and some average field that is created by all magnetized clusters, distributed in the system. This latter field is assumed to be uniform and so is \( H_{\text{ex}} \) itself. However, it is known that the local magnetic field (and subsequently \( \mu_{\text{ex}} \)) in the vicinity of a magnetized spherical body is non-uniform [13]. Thus, Eqs. (10)–(11) are only an approximation. BMM, however, converges to a well-known Maxwell-Wagner formula for the initial permeability of a binary dielectric mixture [39]. In the weak-field limit, it also shows a good agreement with experimental data on the effective permeability of inverse ferroemulsions. This model, however, overestimates experimental results slightly as the applied field increases. Applicability of BMM to our system is to be determined.

In order to close the set of BMM equations, some explicit expressions for magnetization curves \( M_{\text{in}} = M_{\text{in}}(H_{\text{in}}) \) and \( M_{\text{ex}} = M_{\text{ex}}(H_{\text{ex}}) \) are required. For this purpose, the so-called modified mean-field (MMF) theory can be used. It was initially developed to describe static magnetic properties of concentrated ferrofluids [40, 41]. Subsequently, the approach has been extended for the description of the ferrofluid dynamic response [31] as well as magnetic properties of single-domain nanoparticle ensembles immobilized in a solid non-magnetic matrix [32]. Ref. [36] also used the first-order MMF to describe the magnetic component of an inverse ferroemulsion. Within a more accurate second-order MMF approach [42], magnetization of a one-component superparamagnetic material can be written as

\[
M(H) = M_sL\left(\xi_{\text{eff}}\left(\frac{\mu_0mH}{k_BT}\right);\chi_L\right),
\]
\[
\xi_{\text{eff}}(\xi,\chi_L) = \xi + \chi_L(1 + \chi_LL'(\xi)/16) L(\xi),
\]
\[
L(\xi) = \coth \xi - 1/\xi,
\]

where \( M_s = (6/\pi^2 d^3)\mu_0 \) is the material saturation magnetization, \( \varphi \) is the particle volume fraction, \( \chi_L = 8\lambda \varphi \) is the so-called Langevin susceptibility, \( L(\xi) \) is the Langevin function that describes magnetic response of an ensemble of non-interacting dipoles (i.e., at \( \chi_L \ll 1 \)), \( L'(\xi) = dL(\xi)/d\xi \), \( \xi_{\text{eff}} \) is the effective dimensionless field that is acting locally on an arbitrary chosen particle in an ensemble with dipole-dipole interactions. If we assume that both components of our binary mixture can be described by MMF, permeabilities can be written down as

\[
\mu_{\text{in}} = 1 + 3\chi_L^mL\left(\xi_{\text{eff}}(\xi_{\text{in}};\chi_L^{\text{in}})\right), \quad \xi_{\text{in}}^m,
\]
\[
\mu_{\text{ex}} = 1 + 3\chi_L^eL\left(\xi_{\text{eff}}(\xi_{\text{ex}};\chi_L^{\text{ex}})\right), \quad \xi_{\text{ex}}^e = \mu_0mH_{\text{ex}}/k_BT,
\]

where \( \chi_L^{\text{in}} = 8\lambda \varphi_{\text{in}}, \chi_L^{\text{ex}} = 8\lambda \varphi_{\text{ex}}, \xi_{\text{in}} = \mu_0mH_{\text{in}}/k_BT, \)

\[ \xi_{\text{ex}} = \mu_0mH_{\text{ex}}/k_BT. \]

IV. RESULTS AND DISCUSSION

A. Equilibrium magnetization of a mixture in a solid carrier

Magnetization curves for a superparamagnetic cluster embedded in a solid matrix with immobilized nanoparticles are shown in Fig. 2 for different values of \( \lambda \) and \( \varphi_{\text{ex}} \). The first noticeable feature of magnetization curves is that at any given \( \lambda \) an increase in \( \varphi_{\text{ex}} \) leads to a qualitative change in how the system magnetization relates to the Langevin function. Langevin magnetization corresponds to a system of non-interacting dipoles. So, if the normalized magnetization is lower than corresponding Langevin value, it means that dipole-dipole interactions hinder the overall magnetic response. Vice versa, magnetization higher than the Langevin value indicates that dipole-dipole interactions play a reinforcing role. It is known that equilibrium magnetostatic response of superparamagnetic clusters in an empty space always lies below the Langevin curve [38] – this is the result of the demagnetization effect. Similar behavior is observed in our system for a cluster in a diluted medium with \( \varphi_{\text{ex}} = 0.002 \). However, as the concentration of particles in the surrounding medium increases (and as the magnetic permeability of the medium \( \mu_{\text{ex}} \) becomes closer to the permeability of the cluster \( \mu_{\text{in}} \)), demagnetization effects slowly disappear – magnetization of both the cluster and the mixture eventually becomes larger than the Langevin value. Interestingly enough, at \( \varphi_{\text{ex}} \geq 0.05 \) and \( \lambda \geq 3 \) the impact of dipole-dipole interactions on the mixture magnetization depends non-monotonically on the field – while the initial section of the magnetization curve is larger than that of the Langevin function, simulation points eventually fall below \( L(\xi) \) in the saturation regime.

As for the theoretical predictions, it is seen that the combination of BMM and MFT gives very accurate predictions for the initial slope of magnetization curves in
FIG. 2. Equilibrium magnetization curves of a superparamagnetic mixture in a solid carrier. The first row (panels (a)–(c)) demonstrates dependencies of a normalized magnetization (or, identically, of a normalized magnetic moment) of the whole system $M_{tot}$ on the Langevin parameter $\xi_0$. Insets in (a)–(c) show the difference between $M_{tot}$ values from the corresponding panels and the Langevin function $L(\xi_0)$. The latter is indicated on the main panels with dotted lines. The second row (panels (d)–(f)) shows corresponding values of the cluster normalized magnetic moment $M_{cl}$. Different columns correspond to different dipolar coupling parameters: (a), (d) $\lambda = 1$; (b), (e) $\lambda = 3$; (c), (f) $\lambda = 5$. Particle volume fraction in the surrounding medium $\varphi_{ex}$ is indicated by color (see colorbar). Simulation results are shown with circles (transparent lines connecting them are guides for eyes), solid lines are predictions from BMM model [Eqs. (10)-(16)] combined with MMF expressions for magnetic permeabilities [Eqs. (20)-(21)]. Dashed lines are “corrected” BMM predictions with permeabilities values directly extracted from auxiliary simulations of one-component superparamagnetic systems rather than from MMF.

the whole investigated parameter ranges. However, as the field increases, theory and simulation data start to diverge rapidly. The larger $\varphi_{ex}$ and/or $\lambda$ reinforce the discrepancy. Theoretical (solid) curves in Fig. 2 are always above simulation points at $\xi_0 > 1$. At $\varphi_{ex} = 0.15$ and $\lambda = 5$, the error between numerical and theoretical values of the mixture magnetization reaches almost 20% of the corresponding saturation value.

To understand the reason for the discrepancy between theory and simulations, a set of auxiliary simulations was performed. We simulated a one-component ensemble of immobilized nanoparticles randomly and uniformly distributed in a standard cubic box with 3D periodic boundary conditions. Ensemble of $N = 2000$ particles was considered. Using simulation data, a non-linear magnetic permeability of the ensemble was calculated as a function of the field $\xi$ at different $\lambda$ and particle volume fractions $\varphi$. The results are demonstrated in Fig. 3 in comparison with MMF predictions. It can be seen that while MMF mostly predicts correct zero-field permeability values, at large fields it overestimates $\mu$. In more details this feature of immobilized superparamagnetic ensembles was discussed in Ref. [38]. To take it into account the following procedure was performed. Calculated permeability of a one-component system were interpolated (with cubic splines) and then put in BMM instead of MMF predictions Eqs. (20) and (21). The results of this procedure are shown in Fig. 2 with dashed lines. We can see that the accuracy of BMM with “corrected” permeabilities improves drastically. New theoretical curves closely follow $M_{tot}$ dependencies. The magnetization curves for the cluster still overestimate numerical results but it is much better than MMF for $\lambda \geq 3$ and $\varphi_{ex} \geq 0.05$. The probable reason for the remaining discrepancy is the inherent BMM assumption that the magnetic field $H_{ex}$ and permeability of the surrounding medium $\mu_{ex}$ are constant and uniform in cluster vicinity, which is not correct at large enough applied fields [13]. Thus, the agreement
with simulation potentially can only be improved by directly solving a nonlinear magnetostatic boundary-value problem and correctly determining the magnetic field distribution in the system. However, this task is beyond the scope of the present paper.

B. Equilibrium magnetization of a mixture in a liquid carrier

Now let us consider a different type of a binary mixture – a superparamagnetic nanocluster submerged in a suspension of magnetic nanoparticles in a non-magnetic liquid matrix. Essentially, a nanocluster in a ferrofluid or in a very loose gel, in which the cluster is too large to diffuse, but a dispersed phase is not constrained [43]. The magnetization curves for this case are shown in Fig. 4. The first thing that is seen here is that the magnetization curves in Fig. 4 are exactly the same as in Fig. 2. At $\lambda = 1$, these curves actually describe simulation data for LCM quite well – better than the data for SCM (compare insets in Fig. 2(a) and Fig. 4(a)). But already at $\lambda = 3$ the agreement breaks down. Surprisingly, the error does not increase with $\varphi_{ex}$ as in SCM case – the strongest disagreement between theory and simulations takes place at intermediate and low concentrations. For $\lambda = 3$ and $\varphi_{ex} = 0.05$, theoretical predictions are incorrect both for initial and saturation portions of the LCM magnetization curve (Figs. 4(b), (e)). At $\lambda = 5$, the strongest disagreement takes place at even smaller concentrations, $\varphi_{ex} = 0.002$ (Figs. 4(c), (f)).

In order to improve the agreement, the same procedure was employed as for SCM. Namely, an auxiliary set of simulations of a one-component superparamagnetic system was performed. This time, the one-component system was a liquid suspension of single-domain particles. The results for a non-linear magnetic permeability of this system at different particle concentrations and dipolar coupling constants are given in Fig. 5. Comparing it to Fig. 3, we can see that the relation between actual permeability and MMF predictions for liquid and solid one-component superparamagnets is completely opposite. For solid systems, zero-field permeabilities are correctly described by MMF, but the theory overestimates the magnetic response as the field increases. These features of solid superparamagnets are well documented in the literature [38, 44]. For a liquid, zero-field permeabilities are larger than MMF predictions, but in strong fields the agreement significantly improves. This behavior can be attributed to the particle self-assembly, which is not taken into account within the MMF framework. It is known that magnetic particles with sufficiently strong dipole-dipole interactions tend to form chain-like aggregates in viscous [45] and even in soft elastic environments [46]. In monodisperse ferrofluids, the chain formation increases the initial magnetic response [47], but under saturation condition the influence of chains on the magnetization reduces [48].

Once again, numerically obtained permeability curves were interpolated with cubic splines and then used within BMM approach instead of MMF predictions Eqs. (20) and (21). The results of this correction are shown in Fig. 4 with dashed lines. Unfortunately, the correction no longer gives the same accuracy boost as for SCM. In fact, it only improves the initial slope of the magnetization curves. But at large fields, simulation results persistently lie above the predictions of the corrected BMM. It is most clearly demonstrated by $M_{tot}$ and $M_{cl}$ dependencies for $\lambda = 5$ and $\varphi_{ex} = 0.002$ (Fig. 4(c), (f)).

So, it can be deduced that some qualitative change is happening in LCM system, as the field increases:

- it leads to a significant increase of normalized magnetic moments $M_{tot}$ and $M_{cl}$;
- it cannot be explained within BMM approach;
- it is more pronounced at larger $\lambda$ and smaller $\varphi_{ex}$;
- it does not take place in SCM.

\[ \mu = 1 + \frac{M(H)}{H} \]

FIG. 3. Field dependencies of the magnetic permeability for a one-component ensemble of randomly distributed immobilized magnetic nanoparticles. Solid lines are MMF theory predictions [Eqs. (17)-(18)], symbols are simulation results. Different panels correspond to different dipolar coupling constants: $\lambda = 3$ (a) and 5 (b). Particle volume fractions are indicated by color.
FIG. 4. Equilibrium magnetization curves for a superparamagnetic mixture in a liquid carrier. The notation is identical to Fig. 2. Note that colored solid curves corresponding to MMF predictions are also exactly the same as in Fig. 2.

FIG. 5. Field dependencies of the magnetic permeability for a one-component ensemble of magnetic nanoparticles suspended in a liquid matrix (i.e., particles are subjected to a translational Brownian motion). The notation is identical to Fig. 3.

To get a better understanding of what is happening here, a deeper analysis of the system microstructure is presented below.

C. Field-controlled haloing in a liquid carrier

Let us look closely on the behavior of the simulated LCM system at $\lambda = 5$ and $\varphi_{\text{ex}} = 0.002$ — i.e., in the parameter ranges, where the deviations from theoretical magnetization curves are most pronounced. Corresponding simulation snapshots are collected in Fig. 6 for different values of the applied field strength. At a relatively small field, $\xi_0 = 1$, free nanoparticles form chain-like structures, as is expected at $\lambda = 5$ [47]. The presence of a cluster does not produce any clearly visible effects on the system microstructure. However, already at $\xi_0 = 2$ and, especially, at $\xi_0 = 4$ a significant change takes place — particles (or rather, particle chains) start to concentrate near the nanocluster poles forming clouds stretched along the field direction.

The described phenomenon is qualitatively reminiscent of the so-called “haloing” effect, experimentally observed in bimodal magnetorheological fluids [21, 49]. The only difference is that in the latter systems superparamagnetic nanoclusters form thick clouds (or “halos”) around a magnetizable microsphere. On an even larger scale...
the phenomenon was reproduced in Ref. [50]: authors observed the condensation of drop-like aggregates of a phase-separated ferrofluid on the surface of a millimeter-sized iron sphere. The physical reason behind this halo formation in both cases is the phenomenon of magnetophoresis – i.e., the motion of magnetic nanoparticles in a gradient magnetic field [27, 51]. The source of the inhomogeneous field in our problem is the magnetized nanocluster [13]. The stronger the applied field, the stronger the cluster’s own field gradient. This gradient is directed towards poles of the cluster, where free nanoparticles and nanoparticle chains tend to accumulate.

It is known that the transport of magnetic nanoparticles in a viscous medium is affected strongly by interparticle interactions [52, 53]. Namely, dipole-dipole interactions, controlled by \( \lambda \), are acting as effective attraction between particles. They decrease the gradient diffusion coefficient of the system and make it much easier to create a highly inhomogeneous particle distribution with a given applied field. The effect of dipole-dipole interactions on particle transport is typically most pronounced at intermediate average concentrations \( \varphi \leq 0.1 \). In more dense systems, the steric repulsion (i.e., the excluded volume effect) starts to dominate and substantially increases the gradient diffusion coefficient. To put it simply, it is hard to create a noticeable concentration gradient in a highly concentrated system. All these theoretical considerations are well illustrated and validated by LCM concentration maps shown in Fig. 7. First, halos concentration increases with \( \lambda \). At \( \varphi_{ex} = 0.002 \) and \( \lambda = 5 \), the local concentration of particles near cluster poles is actually comparable with the cluster concentration itself (\( \varphi_{in} = 0.3 \)) and two order of magnitude higher than near the cluster “flanks”. Thus, the situation can be interpreted as follows – the cluster, which is spherical in small fields, start to absorb free particles with increasing \( \xi_0 \) and turns into an elongated aggregate aligned with the field. As the aggregate shape changes, its demagnetization factor [\( \kappa \) in Eqs. (10)-(11)] decreases. It is very similar to the behavior of magnetic droplets in ferroemulsions [34], and can explain the anomalous increase of the cluster magnetization seen in Fig. 4(f). The haloing is still present at larger average concentrations. However, an important difference is that at higher average volume fractions the inhomogeneity of the local concentration de-
creases. In the most dense environment with the average particle concentration $\varphi_{ex} = 0.15$, the local particle concentration near cluster surface is always $\varphi_{ex,loc} \geq 0.1$. Correspondingly, variations of $\mu_{ex}$ in the cluster vicinity are getting smaller. As the result, BMM (which assumes the system homogeneity) works much better for concentrated LCM samples.

V. CONCLUSIONS

In this work, equilibrium magnetic response of a binary superparamagnetic mixture is studied both theoretically and numerically (with the help of Langevin dynamic simulations). One component of the mixture is a spherical nanocluster, consisting of immobilized magnetically-isotropic single-domain particles. The cluster is submerged in a superparamagnetic medium, which itself constitutes an ensemble of single-domain particles in a non-magnetic matrix. Two cases are separately considered. In the first case (SCM), particles of the surrounding medium are spatially immobilized, although they fully retain rotational degrees of freedom. This case allows us to neglect possible effects of Brownian motion and particle aggregation. In the second case (LCM), particles in the medium have both translation and rotational degrees of freedom. It is shown that magnetostatic response of the SCM system can be accurately described theoretically within BMM approach [Eqs. (10)-(16)], if the nonlinear permeabilities of individual mixture components are known. It is also shown that MMF predictions for permeabilities [Eqs. (20)-(21)] give accurate description of the simulation data only at relatively small values of the dipolar coupling constant ($\lambda \leq 1$). The situation changes qualitatively for LCM system. If the average particle concentration in the medium is low enough, magnetization of the mixture grows anomalously fast with the field (compared to BMM prediction). The apparent reason for this growth is the so-called halloing effect: the gradient field of the magnetized nanocluster leads to the local redistribution of particles in the surrounding medium. It is shown that particles form concentrated clouds near the cluster poles, this way effectively reducing the demagnetization effect and making it more susceptible to the applied field. A strong dependence of the halloing effect on the intensity of dipole-dipole interactions is revealed.

We can conclude that an accurate theoretical description of the magnetostatic response of a binary superparamagnetic mixture at $\lambda > 1$ cannot simply assume the spatial homogeneity of the systems magnetic properties. The local inhomogeneity of the cluster field and the subsequent drift-diffusion particle transport must be explicitly taken into account. In practice, it will require the solution of a combined magneto-diffusive boundary value problem, similar to those previously considered in Refs. [54, 55]. The solution of this problem is left for future studies.

Appendix A: Approximation of magnetically-isotropic nanoparticles

Let us give here a more detailed explanation of our particles being “magnetically-isotropic”.

The simplest and most common model for an internal magnetic anisotropy of single-domain particles is the easy axis anisotropy [56]. It assumes that the particle possesses a special internal direction (easy axis), which can be characterized by a unit vector $\hat{n}$. The orientational coupling between the axis and the magnetic moment of any given particle is described by the potential

$$U_a = -Kv(\hat{m} \cdot \hat{n})^2,$$  \hspace{1cm} (A1)

where $K$ is the particle anisotropy constant, $\hat{m} = \hat{m}/m$. The interplay between anisotropy and thermal fluctuations is described by the dimensionless anisotropy parameter

$$\sigma = \frac{Kv}{k_B T}.$$  \hspace{1cm} (A2)

For a 10 nm particle with $K \sim 10^4$ J/m$^3$, the anisotropy parameter is $\sigma \sim 1$.

It is known, that the variation in $\sigma$ strongly affects the dynamic magnetic response of single-domain particles in different matrices [57, 58]. However, in this work we are interested only in the equilibrium magnetic response to a static applied field. And it is known that equilibrium magnetization curves of superparamagnetic particles suspended in a liquid simply do not depend on $\sigma$ [32]. Situation becomes more complicated, if particles are immobilized in a solid carrier. In principle, now one has to take into account the “magnetic texture” of the system, i.e., the specific orientational distribution of particles’ easy axes. The texture can be created by applying a strong field during the synthesis stage and can have a major impact on the system magnetic response [33, 59]. However, non-textured composites with random and uniform distribution of easy axes are more similar to liquid superparamagnets – their initial magnetic response also does not depend on the anisotropy parameter $\sigma$ [32, 60]. Increasing $\sigma$ can lower magnetic response at larger fields.
(at \( \xi_0 > 2 \)), but it will not affect the magnetization curve qualitatively [38]. Taking all said into consideration, we decided to investigate here only the limiting case \( \sigma \ll 1 \), i.e., in zero field all internal orientations of magnetic moments are equiprobable. Such approach allows us to considerably simplify both the theoretical treatment and the simulation protocol. We believe that all the results obtained here for magnetically-isotropic solids with finite \( \sigma \) can be extrapolated to liquids and non-textured systems.

**Appendix B: Simulation details**

In a numerical realization of our mixture model, we consider a cubic simulation box with length \( l = V_{tot}^{1/3} \). The cluster is placed in the center of this box. Its position does not change during the simulation. 3D periodic boundary conditions are imposed on a box. The field is directed along \( Z \)-axis. All the results reported are obtained using ESPResSo 4.1.4 simulation package [61].

Rotational motion of the \( i \)-th particle is governed by the Langevin equation

\[
J^* \frac{d\vec{\omega}^*_i}{dt^*} = \vec{\tau}^*_i - \gamma^* R \vec{\omega}^*_i + \vec{\eta}^*_i, \quad \frac{d\vec{m}^*_i}{dt^*} = \vec{\omega}^*_i \times \vec{m}^*_i. \tag{B1}
\]

For LCM, translational motion of the \( i \)-th particle in a viscous carrier is additionally described by an analogous equation

\[
\frac{d\vec{\tau}^*_i}{dt^*} = \vec{f}_i^* - \gamma^* R \vec{v}^*_i + \vec{\eta}^*_i. \tag{B2}
\]

All simulation are performed using reduced quantities, denoted here with the asterisk. They are formally introduced through the usage of three parameters: the thermal energy \( k_B T \), the diameter of a single particle \( d \), and the mass of a single particle \( M \). Specifically, \( \vec{v}^*_i = \vec{v} \sqrt{M/k_BT} \) and \( \vec{\omega}^*_i = \vec{\omega} \sqrt{Md^2/k_BT} \) are the reduced linear and angular velocities, correspondingly. \( J^* = J/2Md^2 \) is the reduced moment of inertia, \( \gamma^* T = \gamma T \sqrt{d^2/2Mrk_B T} \) and \( \gamma^* R = \gamma R \sqrt{1/d^22Mrk_BT} \) are the reduced translational and rotational friction coefficients, \( \vec{\eta}^*_R \) and \( \vec{\eta}^*_T \) are the random force and torque, that have zero mean values and satisfy the standard fluctuation-dissipation relationship [62]

\[
\langle \eta^*_{\alpha}(t_i^*) \eta^*_{\beta}(t_j^*) \rangle = 2\gamma^* T \delta_{\alpha\beta} \delta^*(t_1^* - t_2^*), \tag{B3}
\]

\( \alpha \) and \( \beta \) denote Cartesian vector components, \( \delta^*(t^*) \) is the Dirac delta function, \( \delta_{ij} \) is the Kronecker delta, the reduced time is \( t^* = t \sqrt{k_BT/Md^2} \).

\( \vec{\tau}^*_i = \mu_0 \left[ \vec{m}^*_i \times \left( \vec{H}_0 + \vec{H}_{dd}(i) \right) \right]/k_BT \) is the total reduced magnetic torque acting on a given particle, \( \vec{H}_{dd}(i) = -(1/\mu_0) \sum_{j\neq i} U_{dd}(i,j)/d\vec{m}^*_i \) is the sum of all dipolar fields in the particle center, \( \vec{f}_i^* = -(d/k_BT) \sum_{j\neq i} \partial(U_{dd}(i,j) + U_{WCA}(i,j))/\partial \vec{r}^*_i \) is the total reduced force on the particle, \( U_{WCA}(i,j) \) is the Weeks-Chandler-Andersen (WCA) pair potential that models the steric repulsion between particles [63]:

\[
U_{WCA}(i,j) = \begin{cases} U_{LJ}(r_{ij}) - U_{LJ}(r_{cut}), & r_{ij} < r_{cut} \\ 0, & r_{ij} \geq r_{cut} \end{cases}, \tag{B4}
\]

\[
U_{LJ}(r) = 4\varepsilon \left[ \left( \frac{d}{r} \right)^{12} - \left( \frac{d}{r} \right)^{6} \right], \tag{B5}
\]

where \( U_{LJ} \) is the Lennard-Jones potential, \( r_{cut} = 2^{1/6}d \).

The forces and torques due to long-range dipole-dipole interactions are computed using the dipolar P^3M algorithm with "metallic" boundary conditions [64]. All the results are reported for \( J^* = \gamma^* R = \gamma^* T = \varepsilon^* = 1 \), simulation time step is \( \Delta t^* = 0.01 \). Typically, the first \( 2 \times 10^{5} \) time steps are used for the system equilibration, and the subsequent production run lasts for at least another \( 8 \times 10^{5} \) time steps.
